To assess the viability and physiologic functionality of a cell-seeded device to replace the filtration, transport, metabolic, and endocrinologic functions of the kidney in acutely uremic dogs, researchers introduced a synthetic hemofiltration device combined with a renal tubular cell therapy device (containing porcine renal tubules in an extracorporeal perfusion circuit). Levels of potassium and blood urea nitrogen (BUN) were controlled during treatment with the device. The fractional reabsorption of sodium and water was possible, and active transport of potassium, bicarbonate, and glucose and a gradual ability to excrete ammonia were observed. These results demonstrated the technologic feasibility of an extracorporeal assist device that is

**FIG. 54.3.** Creation of kidney tissue from therapeutic cloning and tissue-engineering strategies. **(A)** Illustration of the tissue-engineered renal unit. **(B)** Renal unit seeded with cloned cells, three months after implantation, showing the accumulation of urinelike fluid. **(C)** There was a clear unidirectional continuity between the mature glomeruli, their tubules, and the polycarbonate membrane. **(D)** Elispot analyses of the frequencies of T-cells that secrete IFN-gamma after primary and secondary stimulation with allogeneic renal cells, cloned renal cells, or nuclear donor fibroblasts.

reinforced by the use of proximal tubular cells (Humes *et al.*, 1999).

Using similar techniques, a tissue-engineered bioartificial kidney — consisting of a conventional hemofiltration cartridge in series with a renal tubule-assist device containing human renal proximal tubule cells — was used in patients with acute renal failure in the intensive care unit. Initial clinical experience with the bioartificial kidney and the renal tubule-assist device suggests that such therapy may provide a dynamic and individualized treatment program as assessed by acute physiologic and biochemical indices (Humes *et al.*, 2003).

#### *In Vivo* Renal Structures

Another method of improving renal function involves augmenting renal tissue with kidney cell expansion *in vitro* and subsequent autologous transplantation. The feasibility of achieving renal cell growth, expansion, and *in vivo* reconstitution with tissue-engineering techniques has been explored.

Most recently, an attempt was made to harness the reconstitution of renal epithelial cells to generate functional

nephron units. Renal cells harvested and expanded in culture were seeded onto a tubular device constructed from a polycarbonate membrane connected at one end to a Silastic catheter terminating in a reservoir. The device was implanted into athymic mice. Histological examination of the implanted devices over time revealed extensive vascularization, with formation of glomeruli and highly organized tubulelike structures. Immunocytochemical staining confirmed the renal phenotype. Yellow fluid consistent with the makeup of dilute urine in its creatinine and uric acid concentrations was retrieved from inside the implant (Yoo *et al.*, 1996). Further studies using nuclear transfer techniques have been performed showing the formation of renal structures in cows (Fig. 54.3) (Lanza *et al.*, 2002). Challenges facing this technology include the expansion to larger, three-dimensional structures.

## VI. ADDITIONAL APPLICATIONS

Tissue engineering and cell therapy hold promise for a number of additional genitourinary applications.

**FIG. 54.4.** Tissue-engineered bulking agent. Chondrocytes are harvested and combined with alginate *in vitro*, and the suspension is injected cystoscopically as a bulking agent to treat urinary incontinence.

### Fetal-Tissue Engineering

Improved prenatal diagnostic techniques have led to the use of intervention before birth to reverse potentially life-threatening processes. Several strategies may be pursued to facilitate the future prenatal management of urologic disease. Having a ready supply of urologic-associated tissue for surgical reconstruction at birth may be advantageous.

Theoretically, once the diagnosis of the pathologic condition is confirmed prenatally, a small tissue biopsy could be obtained under US guidance. These biopsy materials could then be processed and the various cell types expanded *in vitro*. Using tissue-engineering techniques, reconstituted structures *in vitro* could then be readily available at the time of birth for reconstruction (Fauza *et al.*, 1998).

### Injectable Therapies

Both urinary incontinence and vesicoureteral reflux (VUR) are common conditions affecting the genitourinary system that can be treated with injectable bulking agents. The ideal substance for endoscopic treatment of VUR and incontinence should be injectable, nonantigenic, non-migratory, volume stable, and safe for human use.

Animal studies have shown that chondrocytes can easily be harvested and combined with alginate *in vitro*; the suspension can easily be injected cystoscopically; and the elastic cartilage tissue formed is able to correct VUR without any evidence of obstruction (Atala, 1994). The first human application of cell-based tissue-engineering technology for urologic applications occurred with the injection of chondrocytes for the correction of VUR in children and for urinary incontinence in adults (Fig. 54.4) (Bent *et al.*, 2001; Diamond and Caltamone, 1999).

With cell therapy techniques, the use of autologous smooth muscle cells was explored for both urinary incontinence and VUR applications (Cilento and Atala, 1995).

The potential use of injectable, cultured myoblasts for the treatment of stress urinary incontinence (SUI) has also been investigated. Use of injectable muscle precursor cells has also been studied for treatment of urinary incontinence

due to irreversible urethral sphincter injury or maldevelopment (Yiou *et al.*, 2003). A clinical trial involving the use of muscle-derived stem cells (MDSC) to treat SUI has also been performed with good results. Biopsies of skeletal muscle were obtained, and autologous myoblasts and fibroblasts were cultured. Under US guidance, myoblasts were injected into the rhabdosphincter, and fibroblasts mixed with collagen were injected into the submucosa. One year following injection, the thickness and function of the rhabdosphincter had significantly increased, and all patients were continent (Strasser *et al.*, 2004). These are the first demonstrations of the replacement of both sphincter muscle tissue and its innervation by the injection of muscle precursor cells.

In addition, injectable muscle-based gene therapy and tissue engineering were combined to improve detrusor function in a bladder injury model and may have potential as a novel treatment option for urinary incontinence (Huard *et al.*, 2002).

### Testicular Hormone Replacement

Patients with testicular dysfunction require androgen replacement for somatic development. Conventional treatment consists of periodic intramuscular injections of chemically modified testosterone or, more recently, skin patch applications. However, long-term nonpulsatile testosterone therapy is not optimal and can cause multiple problems, including erythropoiesis and bone density changes.

A system was designed wherein Leydig cells were microencapsulated for controlled testosterone replacement. Purified Leydig cells were isolated and encapsulated in an alginate-poly-L-lysine solution. The encapsulated Leydig cells were injected into castrated animals, and serum testosterone was measured serially; the animals were able to maintain testosterone levels in the long term (Machluf *et al.*, 1998). These studies suggest that microencapsulated Leydig cells may be able to replace or supplement testosterone in situations where anorchia or testicular failure is present.

## VII. CONCLUSION

Tissue-engineering efforts are currently being undertaken for every type of tissue and organ within the urinary system. Most of the effort expended to engineer genitourinary tissues has occurred within the last decade. Tissue-engineering techniques require a cell culture facility designed for human application. Personnel who have mas-

tered the techniques of cell harvest, culture, and expansion as well as polymer design are essential for the successful application of this technology. Before these engineering techniques can be applied to humans, further studies need to be performed in many of the tissues described. Recent progress suggests that engineered urologic tissues and cell therapy may have clinical applicability.

### I. INTRODUCTION

Mesenchymal stem cells (MSCs) are nonhematopoietic progenitor cells found in adult tissues, and they are characterized by their extensive proliferative ability in an uncommitted state and the potential to differentiate along various lineages of mesenchymal origin in response to appropriate stimuli. Because of these properties and the ease of their isolation and *in vitro* expansion, MSCs are naturally considered an attractive candidate progenitor cell type for tissue-engineering applications. Since their discovery in the late 1960s, the burgeoning field of MSC investigation has yielded increasing knowledge about their biology, which has in turn provided tools for controlling their activity and cell fate, aspects critical for their use in tissue engineering. MSCs can easily be isolated from an increasing number of adult tissues, and they have been shown to differentiate into cells indicative of various mesenchymal lineages, including cellular phenotypes representative of the musculoskeletal tissues, such as cartilage, bone, muscle, ligament, and tendon. A plethora of factors control the extensive proliferative and multipotent differentiation capacity of MSCs, including growth factors, cytokines, hormones, various signaling molecules, and transcription factors. For tissue engineering of musculoskeletal tissues, their primary functions demand specific tissue form and mechanical strength, and the success of the outcome is dependent on the critical factors of scaffolds, cells, and environmental cues. Optimizing these three factors in musculoskeletal-tissue engineer-

ing, by exploiting our current knowledge on controlling MSC differentiation, has produced promising results in generating engineered tissue replacements for cartilage, bone, osteochondral, and other musculoskeletal tissues using MSCs, although there is clearly room for significant knowledge-based improvements. The current understanding, recent advances, and remaining challenges for the deployment of MSCs for musculoskeletal-tissue-engineering applications constitute the subject of this chapter.

### II. MSC BIOLOGY RELEVANT TO MUSCULOSKELETAL-TISSUE ENGINEERING

An ideal cell source for tissue engineering should exhibit the following characteristics: availability and easy access of the source cells, capacity for extensive self-renewal or expansion to generate sufficient quantity, capacity to differentiate readily into cell lineages of interest on instructive differentiation cues, and lack of or minimal immunogenic or tumorigenic ability. We discuss the intrinsic properties of MSCs that determine their behavior as well as external factors that affect the growth, differentiation, and the developmental outcomes of MSCs.

#### MSC Identification

MSCs were first described by Friedenstein and colleagues in 1966 as a population of adherent, colony-forming,

**FIG. 55.1.** Multilineage differentiation potential of mesenchymal stem cells. MSCs are able to differentiate into cell types of multiple lineages under appropriate conditions, including bone, cartilage, adipose, muscle, tendon, and stroma. The arrows are presented as bidirectional, suggesting that differentiated mesenchymal stem cells are capable of dedifferentiation and transdifferentiation (Song and Tuan, 2004). Adapted from Tuan *et al.* (2003).

fibroblast-like cells able to undergo osteogenic differentiation (Friedenstein *et al.*, 1966). MSCs have since been shown to possess the capacity to differentiate into cells characteristic of several mesenchymally derived tissues, including cartilage, bone, fat, muscle, tendon, and hematopoietic-supporting marrow stroma (Fig. 55.1). In addition to these mesenchymal lineages, MSCs can differentiate into other tissue types, including hepatocytes and neural tissues (Caplan, 1991; Jiang *et al.*, 2002; Pittenger *et al.*, 1999; Prockop, 1997; Suon *et al.*, 2004).

Experimentally, MSCs are identified by the expression of a number of surface markers, including STRO-1, SB-10, SH3, and SH4 antigens as well as Thy-1 (CD90), TGF- $\beta$  receptor type III endoglin (CD105), hyaluronic acid receptor CD44, integrin  $\alpha$ 1 subunit CD29, CD133, p75LNGFR, and activated leukocyte-cell adhesion molecules (ALCAM, CD166). MSCs are negative for the hematopoietic markers, CD34, CD45, and CD14. SH3, SH4, and STRO-1 antibodies recognize antigens that are present on mesenchymal stem cells but not hematopoietic cells (for review, see Baksh *et al.*, 2004; Gregory *et al.*, 2005; Tuan *et al.*, 2003). However, these are not expressed exclusively by MSCs and are found on other cell types as well. To date, there is no one single marker or a combination of markers that has been shown to be specific and exclusive to MSCs. Therefore it remains a challenge to isolate MSCs specifically from a mixed cell population. Frequently, a combination of antibodies is used

to characterize the MSC phenotype retrospectively. Inconsistency in the literature on the growth characteristics and differentiation potential of MSCs underscores the need for a functional definition of MSCs. At present, there is lack of a unifying definition as well as information on specific markers that define the cell types characterized as MSCs, with the sole definition being their ability (1) to proliferate to self-renew and remain in an undifferentiated state until provided the signal to do so, and (2) to differentiate along specific mesenchymal lineages when induced to do so (Fig. 55.1).

### Tissue Sources of MSCs

Bone marrow remains the best-studied tissue source for MSCs. In addition, MSC-like cells have been identified in a number of other tissues, including adipose, periosteum, synovial membrane, muscle, dermis, deciduous teeth, pericytes, trabecular bone, articular cartilage, immobilized peripheral blood, cord blood, and placenta (Baksh *et al.*, 2004; Gregory *et al.*, 2005; Tuan *et al.*, 2003) (Table 55.1). The endogenous functions of these stem cells in these various tissues remain unclear, although they are generally thought to participate in local tissue repair and regeneration. In addition, bone marrow MSCs can give rise to stromal cells that support hematopoiesis *in vitro* and *in vivo*, possibly through providing extracellular components as well as various growth factors and cytokines (Majumdar *et al.*, 2000).

Although bone marrow is relatively easily accessible, the potential donor site morbidity, pain, and low cell incidence have prompted researchers to find alternative sources for MSC isolation to meet the demand of cell therapy. In addition to easy accessibility, MSC yield, proliferation rate, multipotency, and differentiation potential determine the usefulness of MSCs from different tissue origins. Although MSCs from different tissues show similar phenotypic characteristics, it is not clear if these are the same MSCs, and they clearly show different propensities in proliferation and differentiation. For example, a recent study comparing human MSCs derived from bone marrow, umbilical cord blood, and adipose tissue showed that adipose tissue contained the highest number of hMSCs while umbilical cord blood contained the lowest. However, umbilical cord blood-derived MSCs could be cultured longest and showed the highest proliferation capacity, whereas bone marrow-derived MSCs showed the lowest proliferation capacity (Kern *et al.*, 2006). Sakaguchi *et al.* (2005) compared the properties of MSCs isolated from bone marrow, synovium, periosteum, skeletal muscle, and adipose tissue and found significant differences in their differentiation potentials.

MSCs from bone marrow, synovium, and periosteum showed greater chondrogenic activities, with synovium-derived MSCs exhibiting the highest capacity. With regard to osteogenesis, the rate of matrix mineralization was highest in bone marrow-, synovium-, and periosteum-derived MSCs. Therefore, the optimal source of MSCs for therapeutic use for the musculoskeletal system remains to be determined.

In addition to tissue source, donor age and disease stage may directly affect MSC yield, rate of proliferation, and multipotency. There seems to be decreasing MSC number and proliferation rate as well as differentiation potentials with increasing age (Quarto *et al.*, 1995). MSCs isolated from osteoporotic women showed significantly reduced proliferative response and osteogenic differentiation (Rodriguez *et al.*, 1999). With bone marrow MSCs, advanced osteoarthritis (OA) condition, regardless of age, has a significantly deleterious impact on proliferative capacity and chondrogenic and adipogenic activities when compared to healthy donors (Murphy *et al.*, 2002). The potential decrease of MSC quantity and quality with age and disease may limit the use of autologous MSCs in clinical settings, which warrants further study. This indicates the need for using allogeneic MSCs for tissue repair, which might carry the risk of immune rejection and allogeneic reaction by the host. This topic is discussed in detail later.

### MSC Isolation and *In Vitro* Culture

MSCs are rare in bone marrow, occurring with a frequency of 0.001–0.01% of the total nucleated cells (Pittenger *et al.*, 1999). Various protocols of MSC isolation are available, and some are species specific. Human bone marrow MSCs can be isolated by simple direct plating. Frequently, this is performed with the layer of mononuclear cells obtained after Percoll or Ficoll density gradient centrifugation. With time and medium changes, the nonadherent hematopoietic cells are washed away, and MSCs appear as small, adherent, spindle-shaped fibroblast-like cells. Further purification can be performed by either surface marker-based positive selection or negative selection using either magnetic activated cell sorting (MACS) or fluorescence activated cell sorting (FACS). Positive selections have been based on the selection of markers that are expressed by the MSCs (although not exclusively). These include STRO-1, CD105, CD133, and p75LNGFR. Negative selection is based on the exclusion of markers that are expressed by hematopoietic cells, using antibodies against CD34, CD45, and CD11b.

MSCs are normally cultured in Dulbecco's modified eagles medium (DMEM) or  $\alpha$ -minimum essential medium ( $\alpha$ -MEM) supplemented with 10% preselected batches of fetal bovine serum at 37°C with 5% CO<sub>2</sub> in a humidified chamber. After initial expansion, cultures are maintained at densities of 50–10,000 cells/cm<sup>2</sup> (Gronthos *et al.*, 1994; Jiang *et al.*, 2002; Sekiya *et al.*, 2002a). The extensive expansion

sion capacity of MSCs depends on the harvesting techniques, the culture conditions, and the condition and age of the donor. The growth of MSCs exhibits a lag phase of growth, followed by an exponential growth phase and a plateau state when confluent. On subculturing, the same cycle resumes. Microscopically, MSCs exhibit a fibroblast-like morphology under light microscope (Fig. 55.2). There is a wide range in the number of population doublings the MSCs can undergo, with the average maximal value of  $38 \pm$

**FIG. 55.2.** Morphology of human bone marrow–derived mesenchymal stem cells. MSCs exhibit fibroblastic phenotype when maintained in mono-layer culture, as observed by phase contrast microscopy. Bar, 100  $\mu$ m.

4, at which point the cells become large and flatten and become senescent (Table 55.2). The osteogenic potential of MSCs appears to be conserved throughout extensive pas-sage (Bruder *et al.*, 1997). Culture conditions, such as initial seeding density, also play a role in the expansion capacity of MSCs. For example, higher proliferation profiles of MSCs was seen when plated at low initial plating density (1.5–3 cells/ $\text{cm}^2$ ) but not at high density (12 cells/ $\text{cm}^2$ ), resulting in a dramatic increase in the fold expansion of total cells (2000-fold vs. 60-fold increase, respectively) (Colter *et al.*, 2000).

### MSC Self-Renewal and Proliferation Capacity

*In vivo*, MSCs remain in a mitotically quiescent state (G0 stage of the cell cycle), as demonstrated by analysis of fresh bone marrow cell harvests continuously exposed to tritiated thymidine labeling (Friedenstein *et al.*, 1974). BrdU labeling of cells in a human trabecular bone explant culture also reveals that cell proliferation, including that of Stro-1-positive mesenchymal stem/progenitor cells, was inhibited completely within the explant tissue milieu (Song *et al.*, 2005). Since most of the tissues/organs from which MSCs are derived exhibit a relatively slow turnover rate in the adult organism, it is not unreasonable to propose that self-renewal or proliferation of MSCs is normally suppressed *in vivo* in the course of tissue homeostasis, possibly regulated by intrinsic factors present in the tissue microenvironment and/or through direct or indirect interaction with neighbor-ing cells.

*In vitro*, primary MSC cultures exhibit a lag phase of growth, ranging from 24 hours to five days, followed by an exponential phase of four to six days before reaching the

Table 55.2. <i>In vitro</i> population doubling potential of human mesenchymal stem cells			
Cell source	Culture condition	Population doublings	References
Bone marrow	$\alpha$ MEM, 17% FBS, 2 mM L-glutamine	10	Pochampally <i>et al.</i> (2004)

Pancreas	DMEM, 2% FBS, MCDB-201, 10 ng/ml EGF, 1 $\times$ insulin-transferrin selenium, 1 $\times$ linoleic acid BSA, 10 nM Dex, 10 mM ascorbic acid phosphate	30	Hu <i>et al.</i> (2003)

plateau phase, after which cell division slows dramatically. Cell-cycle studies revealed that the majority of the MSCs (between 78.7% and 96.45%) are in the G0/G1 phase of the cell cycle, while a very small fraction of MSCs are engaged in active proliferation. Depending on the tissue source, donor age, and culture conditions, population doubling times of hMSCs vary to a large extent. During the log phase of the cell growth, human MSCs isolated from bone marrow and fetal pancreas exhibited a similar population doubling time, ranging from 10 to 30 hours. On the other hand, post-natal human MAPCs, a subset of MSCs, divide much slower, with a population doubling time of 48–72 hours.

Unlike embryonic stem cells, MSCs do not expand indefinitely *in vitro* when cultured in the presence of serum, which could be due to their intrinsic property as adult stem cells or due to suboptimal culture environment. After extensive propagation, MSCs change their phenotype from a fibroblastic shape to a more flattened morphology with extensive podia and actin stress fiber formation, a phenomenon usually referred to as *replicative senescence*. Consistent with their limited expansion capacity, hMSCs do not express telomerase activity, and their telomere length is reduced as the cells grow older. Furthermore, murine MSCs derived from telomerase knockout mice failed to differentiate into adipocytes and chondrocytes and lost telomere at late passage (Liu *et al.*, 2004). Therefore, telomerase activity and telomere maintenance appear to play a crucial role in maintaining the self-renewal and multidifferentiation potential of MSCs. Indeed, hMSCs stably expressing telomerase reverse transcriptase can undergo 80 (Okamoto *et al.*, 2002; Shi *et al.*, 2002) or 260 (Simonsen *et al.*, 2002) population doublings without growth arrest. In addition, growth factors play a role in the expansion capacity of MSCs. Basic fibroblast growth factor (bFGF) can prolong the replicative capacity of hMSCs and increase total cell numbers by several-fold when included in the basal culture medium.

### Multilineage Differentiation of MSCs

MSC differentiation is tightly controlled by several factors, such as growth factors, hormones, extracellular matrix molecules, and signaling pathways. Relevant to musculoskeletal tissue engineering, *in vitro* chondrogenesis of MSCs, or cartilage formation, is accomplished by culturing the cells in a three-dimensional culture condition, either as pellet culture, micromass cultures, or three-dimensional scaffold, in the presence of a member of the transforming growth factors (TGF- $\beta$ 1, TGF- $\beta$ 2, or TGF- $\beta$ 3 or bone morphogenetic proteins, BMPs). Supplementation with dexamethasone also promotes the expression of chondrocyte phenotype. Chondrogenesis is demonstrated histologically by the expression of genes encoding cartilage matrix components, including aggrecan, collagen types II and IX, and COMP (cartilage oligomeric matrix protein). Control of MSC chondrogenesis is discussed in more detail in the cartilage-tissue-engineering section of this chapter.

Osteogenesis, i.e., bone formation, can be induced *in vitro* by treating MSCs with the synthetic glucocorticoid dexamethasone,  $\beta$ -glycerophosphate, ascorbic acid, and 1,25-dihydroxyvitamin D<sub>3</sub>. Alkaline phosphatase (ALP) activity and calcification of the extracellular matrix are typical markers used for detecting preosteoblasts and mature osteoblasts, respectively. Dexamethasone stimulates MSC proliferation and increases ALP activity of osteogenic hMSCs. However, matrix mineralization occurs only when dexamethasone functions together with  $\beta$ -glycerophosphate and ascorbic acid, and it is further enhanced by 1,25-dihydroxyvitamin D<sub>3</sub>.

Growth factors also play certain osteoinductive roles. For instance, treatment of human MSCs with insulin like growth factor 1 (IGF-1), epidermal growth factors (EGF), and vascular endothelial growth factor (VEGF) increases the activity of ALP and mineralization *in vitro*. On the other hand, platelet-derived growth factor (PDGF) has little inductive effect on hMSC osteogenesis.

Members of the Wnt family of signaling proteins have recently been shown to impact human MSC osteogenesis (Boland *et al.*, 2004; Cho *et al.*, 2006; De Boer *et al.*, 2004). Wnts are a family of secreted cysteine-rich glycoproteins that have been implicated in the regulation of stem cell maintenance, proliferation, and differentiation during embryonic development. In humans, mutations in the Wnt coreceptor, LRP5, lead to defective bone formation. LRP5 gain of function mutation results in high bone mass, where loss of function causes an overall loss of bone mass and strength, indicating that Wnt signaling is positively involved in embryonic osteogenesis. *In vitro*, exposure of human MSCs to Wnt3a-conditioned medium or overexpression of ectopic Wnt3a inhibits osteogenesis. The expression of several osteoblast specific genes, e.g., ALP, bone sialoprotein, and osteocalcin, was dramatically reduced, while the expression of Cbfa1/Runx2, an early osteoinductive transcription factor, was not altered, implying that Wnt3a-mediated canonical signaling pathway is necessary but not sufficient to completely block hMSC osteogenesis. On the other hand, Wnt5a, a typical noncanonical Wnt member, has been shown to promote osteogenesis (Boland *et al.*, 2004). Since Wnt3a promotes MSC proliferation during early osteogenesis, it is very likely that canonical Wnt signaling functions in the initiation of early osteogenic commitment by increasing the osteoprogenitor reservoir, while non-canonical Wnt drives the progression of osteoprogenitor to mature functional osteoblasts. The identity and actions of intracellular mediators of Wnt signaling remain to be elucidated.

### Plasticity of MSCs

Plasticity/transdifferentiation is a process whereby a cell type committed to and progressing along a specific developmental lineage switches into another cell type of a different lineage through genetic reprogramming. As dem-

onstrated by several studies, terminally differentiated cells can switch their phenotype under appropriate stimulations. For example, chondrocytes can become osteocytes (Gentili *et al.*, 1993; Kahn and Simmons, 1977), and adipocytes can convert to osteoblasts (Bennett *et al.*, 1991; Beresford *et al.*, 1992; Bianco *et al.*, 1988). Since all of these cells are the mature progenies of MSCs, the conversion from one to another might reflect the plastic property of MSCs. By using an *in vitro* differentiation strategy, we have demonstrated that human MSCs precommitted to a given mesenchyme cell lineage can transdifferentiate into other cell types in response to inductive extracellular cues (Song and Tuan, 2004). Understanding the molecular mechanisms that control the transdifferentiation potential of MSCs will facilitate the identification of regulatory factors, thus providing tools to manipulate adult stem cells for cell-based tissue-engineering applications.

### MSC Heterogeneity

Individual colonies derived from single MSC precursors exhibit a heterogeneous nature in terms of cell proliferation and multilineage differentiation potential. For instance, only a minor proportion of colonies (17%) derived from adult human bone marrow continued to grow beyond 20 population doublings, while the majority of the colonies exhibited early senescence (Gronthos *et al.*, 2003). There is also a marked difference in the differentiation capacity of MSC colonies. For example, Pittenger *et al.* (1999) reported that only one-third of the initial adherent bone marrow-derived MSC clones are multipotent to differentiate along the osteo-, chondro-, and adipogenic pathways (osteo/chondro/adipo). Furthermore, nonimmortalized cell clones examined by Muraglia *et al.* (2000) demonstrated that 30% of the *in vitro* derived MSC clones exhibited a trilineage (osteo/chondro/adipo) differentiation potential, while the remainder displayed a bilineage (osteo/chondro) or unilineage potential (osteo). These observations are consistent with other *in vitro* studies using conditionally immortalized clones. Even derived from a single colony, cells seem to be heterogeneous. Kuznetsov *et al.* (1997) demonstrated that only 58.8% of the single colony-derived clones had the ability to form bone within hydroxyapatite-tricalcium phosphate ceramic scaffolds after implantation in immunodeficient mice. Similar results were reported by using purer populations of MSCs maintained *in vitro* (Gronthos *et al.*, 2003). Taken together, these results suggest that MSCs are heterogeneous with respect to their developmental potential, placing a significant challenge on selecting the most potent cells for clinical application in tissue regeneration.

There exist a number of inconsistencies and discrepancies among currently published results on MSCs, perhaps reflecting the heterogeneity of the population, different isolation and culture methods, as well as the different stimuli used for the differentiation procedures. There has not been

a single MSC specific marker unequivocally to identify MSCs, and there is heterogeneity in MSC populations. Most likely, distinct and unrelated cell types are being studied, and only a subpopulation of the MSCs are true stem cells.

### MSC Effect on Host Immunobiology

Ideally, autologous MSCs would have advantages over allogeneic MSCs for regenerative medicine because autologous MSCs pose few immunological complications. However, due to the rarity of MSCs and also to the possible decrease in quantity as well as quality of the MSCs with age and disease, it is more feasible to consider using allogeneic MSCs for replacing or repairing damaged tissues. Before this is considered acceptable, it is important to understand MSC-elicited host immunological reactions. Allogeneic cells are normally detected and deleted by the host immune systems. However, MSCs have been surprisingly different in this aspect and offer several advantages, including possible suppressing and modulatory effects on host immune response.

The first immunological advantage of MSCs is that they are hypoimmunogenic and can evade host immune system, as shown by several *in vitro* experiments. This makes MSCs attractive for allogeneic transplantation, whose major limitation is host immune rejection. MSCs express low (fetal) to intermediate (adult) major histocompatibility complex (MHC) class I molecules, and do not express MHC class II molecules on their cell surface (Gotherstrom *et al.*, 2004; Le Blanc *et al.*, 2003). The expression of MHC class I molecules helps to protect MSCs from deletion by natural killer cells. The lack of surface MHC class II expression gives the MSCs the potential to escape recognition by alloreactive CD4<sup>+</sup> T-cells. MSCs do contain an intracellular pool of MHC class II molecules that can be mobilized onto the cell surface by treatment with interferon- $\gamma$  (IFN- $\gamma$ ). However, induced surface expression of MHC class II still does not render the MSCs immunogenic (Le Blanc *et al.*, 2003). After differentiation, MSCs continue to express MHC class I but not class II molecules on their cell surface, and they continue to be non-immunogenic (Gotherstrom *et al.*, 2004; Le Blanc *et al.*, 2003).

Experimental evidence suggests that MSCs can interact directly with immune cells and modulate and suppress alloreactivity. MSCs inhibit T-cell proliferation *in vitro* (Bartholomew *et al.*, 2002; Di Nicola *et al.*, 2002; Tse *et al.*, 2003). MSCs do not seem to express costimulatory molecules, CD40, CD40 ligand, B7-1, and B7-2, and probably do not activate alloreactive T-cells (Tse *et al.*, 2003). In fact, MSCs suppress T-cell activation and proliferation. For example, MSCs have been shown to suppress CD4<sup>+</sup> and CD8<sup>+</sup> T-cells in mixed lymphocyte cultures (Di Nicola *et al.*, 2002; Tse *et al.*, 2003). Even though T-cell proliferation can be induced by exogenous costimulation, when they are cocultured with MSCs in the presence of a stimulant, T-cell proliferation is not observed (Tse *et al.*, 2003). MSCs can also induce apo-

ptosis of activated T-cells but not resting T-cells (Plumas *et al.*, 2005). Supporting these observations, Bartholomew (Bartholomew *et al.*, 2002) showed that allogeneic baboon MSCs inhibited the proliferation of lymphocytes *in vitro* and prolonged skin graft survival *in vivo*. In addition to the effect of MSCs on T-cells, MSCs can affect dendritic cell differentiation and maturation and interfere with their function (Beyth *et al.*, 2005; Zhang *et al.*, 2004). They also alter the phenotype of natural killer cells and can suppress the proliferation, cytokine secretion, and cytotoxicity of these cells against MHC class I targets (Sotiropoulou *et al.*, 2006).

In addition to cell-cell interaction mediated inhibition, MSCs are capable of secreting soluble factors to create a local immunosuppressive environment. These factors have been shown to include hepatocyte growth factor (HGF), TGF- $\beta$ 1, IL-10, and prostaglandin E2 (Aggarwal and Pittenger, 2005; Di Nicola *et al.*, 2002). For example, MSCs are shown constitutively to express HGF and TGF- $\beta$ 1. When anti-HGF and anti-TGF- $\beta$ 1 antibodies are included, MSC inhibition on T-cell proliferation is lifted (Di Nicola *et al.*, 2002). IL-10 is a cytokine for regulatory T-cells and can suppress inflammatory immune response. Similarly, IL-10 is shown to be produced either constitutively or increased in coculture, and MSCs can mediate the suppressive activities partially through IL-10 (Aggarwal and Pittenger, 2005; Beyth *et al.*, 2005; Rasmusson *et al.*, 2005). Collectively, these *in vitro* studies have suggested that MSCs can interact with the various subsets of cells of the immune system, alter the response of the immune cells, and shift the response from a pro-inflammatory response to an antiinflammatory response, possibly through inhibition of the pro-inflammatory cytokines, such as IFN- $\gamma$  and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and stimulation of the immunosuppressive cytokines, including IL-10 and prostaglandin E2 (Aggarwal and Pittenger, 2005). The role of secreted factors in the immunoregulatory action of MSCs remains an actively investigated area. Contradictory results exist as to which factors are important for this function. For example, although a role for IL-10, TGF- $\beta$ , and prostaglandin E2 has been suggested, in other studies none of these factors was found to be responsible for the immunosuppressive action of MSCs (Tse *et al.*, 2003). Despite the discrepancies on the mechanism of action, the foregoing studies suggest that MSCs can be transplanted between MHC-incompatible individuals.

The *in vitro* studies showing that MSCs possess immunomodulatory and immunosuppressive activities suggest that MSCs can be potentially used *in vivo* for enhancing the engraftment of other tissues (e.g., hematopoietic stem cells) or for the prophylactic prevention and even possibly as a treatment of graft-versus-host disease, to prevent rejection and to promote transplant and patient survival. However, before MSC treatment can be used as standard therapy on humans, more *in vivo* animal studies need to be performed, and the biology and mechanism of MSC immunomodulation effect need to be better elucidated.

### Safety of Using MSCs for Transplantation

The ability of MSCs to undergo extensive self-renewal via proliferation raises some concern as to whether MSCs, after prolonged *in vitro* culture, can become tumorigenic. Although most MSC transplantations did not show obvious malignant transformation, there has been evidence suggesting otherwise. Rubio *et al.* (2005) showed that although standard short-term *in vitro* culture (six to eight weeks) seems safe, MSCs can undergo spontaneous transformation after long-term culture of four to five months.

The immunosuppressive properties, especially the potential systemic immunosuppressive ability of MSCs, bring caution to the use of MSCs under certain clinical conditions, such as cancer. Using a murine melanoma tumor model, it has been shown that cotransplantation of an MSC cell line (C3H10T1/2) favors tumor growth of subcutaneously injected B16 melanoma cells (Djouad *et al.*, 2003). However, this tumor-promoting effect was not observed in another study of coculture of a rat MSC line, MPC1cE, with rat colon carcinoma cells in a gelatin matrix. In this case, an inhibitory effect of MSCs on the outgrowth of the tumor cells was observed (Ohlsson *et al.*, 2003). The effect of MSCs on tumor growth requires further investigation to rule out the potential side effect of the therapeutic use of MSCs.

## III. MSCs IN MUSCULOSKELETAL TISSUE ENGINEERING

The musculoskeletal system of the human body is designed to sustain and maintain its form and function in the face of enormous load-bearing demands throughout a normally active life. Form and mechanical strength are vital for the function of this system. The mechanical and biochemical properties of the musculoskeletal system that define its structure and function also define the functional requirements of a tissue-engineered substitute. Successful tissue engineering based replacement of native tissues will likely require constructs that possess functional properties similar to those of the native tissues to minimize premature failure. There are two basic approaches in tissue engineering. The first one is *ex vivo* tissue engineering, in which the construct is cultivated *in vitro* to achieve appropriate functionality before implantation. The second approach is *in vivo* tissue engineering, in which the construct is allowed to mature *in vivo* for tissue repair and regeneration. For both approaches, three components govern the eventual outcome of tissue-engineered constructs: appropriate scaffold, instructive environment, and responsive cells.

### Cartilage Tissue Engineering

The need for engineered cartilage arises from the fact that while the tissue often functions well through a lifetime of use, 9% of the U.S. population age 30 and older have osteoarthritis (OA) of the hip or knee. The total cost of OA is estimated at \$28.6 billion per year in the United States alone

(Felson and Zhang, 1998), with over 200,000 knee replacements performed each year. The intrinsic healing capacity of the native tissue is limited, and, given the increasing incidence of OA and the increasing life expectancy of the population, there is a growing demand for novel repair strategies. Effective treatment of cartilage injuries may eliminate or forestall the need for joint replacement, thus enhancing the quality of life.

### General Properties of Articular Cartilage

Articular cartilage is the dense white tissue that lines the surfaces of joints and functions to transmit the high stresses associated with joint motion. The tissue consists of both a solid extracellular matrix (ECM) component as well as a fluid phase (Mow *et al.*, 2005). The solid ECM is composed of a dense network of specialized molecules that engender the unique mechanical properties of the tissue. Collagen content (predominantly collagen type II) of the tissue ranges from 5% to 30% by wet weight, while proteoglycan (PG) content ranges from 2% to 10%. In addition to these major elements, the ECM includes numerous minor collagens (e.g., types VI, IX, and XI) and linking molecules (COMP, hyaluronan, link protein, fibronectin). Together, these elements make up the fluid-filled fibrous network of the cartilage ECM, with larger collagen fibers interwoven throughout an array of large PG aggregates (aggrecan core protein with its covalently linked keratan and chondroitin sulfate moieties) attached to long hyaluronan chains. These core constituents change with age (resulting in the emergence of adult functional properties) and deteriorate with disease processes (such as OA).

The cellular component of cartilage, the chondrocytes, comprises less than 10% of the tissue volume and maintains the cartilage by synthesizing ECM constituents to balance their continual degradation and remodeling. Chondrocytes display a rich transcriptional profile *in situ* reflective of their specialized cartilaginous phenotype, which is lost when these cells dedifferentiate with expansion in monolayer culture. *In situ*, chondrocytes are tuned to the mechanical loading environment, altering rates and location of matrix ECM production with changes in physiologic loading (Guilak and Hung, 2005).

The mechanical properties of articular cartilage underlie its ability to act as a low friction bearing surface over a lifetime of use. The dense, negatively charged PG-rich ECM results in an equilibrium compression modulus of 0.2–1.4 MPa (Mow *et al.*, 2005). The collagen content engenders a tensile modulus that is higher, ranging from 1 to 30 MPa (Woo *et al.*, 1976). One unique feature of cartilage is that under transient or cyclical loading at physiologic frequencies (0.1–2 Hz), interstitial fluid pressure is maintained at elevated values. This fluid pressurization arises with contact and supports >90% of applied stress, shielding the matrix from excess deformation (Soltz and Ateshian, 1998). Fluid pressurization also results in a higher dynamic modulus

than equilibrium modulus, effectively stiffening the tissue with higher frequency loading. Cartilage use arises from movement, with the resulting forces that are multiples of body weight acting on the cartilage, resulting in stresses at the surface of  $\geq 2$  MPa (Brown and Shaw, 1983).

### Cartilage Tissue Engineering with Chondrocytes

When tissue engineering was originally proposed as a strategy for repairing diseased or damaged tissues, it was believed that articular cartilage would be one of the first successes in this new field, owing to its relatively simple composition (possessing a single cell type) and lack of neural and vascular supply. The first approaches focused on the chondrocyte itself, postulating that because these cells make and maintain matrix *in vivo*, exogenous cells should be able to reconstitute the tissue when implanted. Early *in vivo* successes demonstrated enhanced repair when high-density chondrocyte solutions were transplanted to focal defects beneath a periosteal flap (Brittberg *et al.*, 1994), a procedure now commonly referred to as autologous chondrocyte transplantation/implantation (ACT/ACI) and commercialized as the Carticel® method by Genzyme Biosurgery. While questions remain regarding the efficacy and cost effectiveness of this approach, it nevertheless stands as the first clinically available tissue-engineering strategy to enhance cartilage repair.

In addition to using chondrocytes directly as therapeutics, there has been a growing interest in the combination of chondrocytes with a carrier scaffold for *in vivo* implantation or *in vitro* maturation in culture conditions permissive of neotissue growth. Experimental challenges include finding a source of chondrocytic cells, phenotype maintenance, and the provision of an appropriate three-dimensional matrix. Regardless of the chondrocyte transplantation carrier materials used, it should be noted that in nearly all cases, repair is significantly better with cell-seeded scaffolds than with acellular scaffolds alone. Scaffolding materials composed of woven and nonwoven macroporous meshes of biodegradable polymers such as poly-glycolic acid (PGA), poly-lactic acid (PLA), and their copolymers have shown great potential in cartilage-tissue engineering (Vunjak-Novakovic *et al.*, 1999). Recent fabrication technologies have further improved the deployment of such polymers, either by changing the length scales of fiber components to produce nanofibrous scaffolds (Li *et al.*, 2003) or by modifying the deposition methodology to define depth-dependent structural properties (Sherwood *et al.*, 2002).

In addition to fibrous scaffolds, various biocompatible hydrogels have been applied for the *in vitro* and *in vivo* growth of cartilage constructs. These hydrogels include alginates (Paige *et al.*, 1995; Rowley *et al.*, 1999), fibrin gels (Fortier *et al.*, 1997), agarose (Buschmann *et al.*, 1992), collagen type I (Wakitani *et al.*, 1998), collagen type II (Nehrer *et al.*, 1997), photopolymerizing poly(ethylene glycol) (PEG) gels (Elisseff *et al.*, 2002), and, more recently, self-

assembled peptide hydrogels (Kisiday *et al.*, 2002). Continued modifications of these gels, as with the recent modifications of PEG-based hydrogels to introduce a matrix metalloproteinase (MMP)-cleavable linker, may further enhance tissue formation by promoting remodeling of the carrier material as new tissue is deposited (Park *et al.*, 2004). Combinations of scaffold materials (e.g., fibrous and gel scaffolds) may also be valuable in this pursuit.

### Factors Influencing Outcomes of Tissue-Engineered Cartilage

The evolution of a tissue-engineered construct is a time-dependent process, controlled by numerous (and sometimes unanticipated) factors. This creates the difficult engineering problem of construct optimization, and numerous studies have addressed how the variation in such parameters influences the development of biochemical and mechanical properties of the tissue. For example, increasing the seeding density of cells within a scaffold typically results in a more rapid development of construct properties (S. C. Chang *et al.*, 2001). Variations in the amount and formulation of culture media can also have profound effects on chondrocyte biosynthetic activities. For example, increasing the amount of fetal bovine serum (FBS) in growth medium has been shown to enhance the mechanical properties of constructs (Mauck *et al.*, 2003). Specific supplementation with biologically active growth factors found in the synovial fluid can also influence chondrocyte biosynthetic activities and construct maturation. In particular, anabolic factors (those leading to increased production and retention of ECM), including IGF-1, TGF- $\beta$ 1 and - $\beta$ 3, BMP-2, 12, 13, and IL-4, have all been shown to positively modulate the growth of engineered cartilage constructs (Blunk *et al.*, 2002; Gooch *et al.*, 2001). More recently, novel reduced-serum or chemically defined serum-free formulations have been introduced that support the growth of cartilaginous constructs (Kisiday *et al.*, 2002), reducing variability among constructs and enhancing their potential for clinical application by defining media constituents and limiting the inclusion of animal products in the culture process.

In addition to changing cell densities and media formulation, recent cartilage-engineering efforts have focused on the native loading environment as a potential modulator of engineered construct growth. In this so called “functional tissue engineering” approach, bioreactors are designed to recapitulate some portion of the *in vivo* environment in the *in vitro* culture system (Butler *et al.*, 2000). Cartilage may be particularly amenable to this approach, for it is a tissue whose function and form are defined by its physical environment. One of the first bioreactors applied for cartilage-tissue engineering was the rotating-wall vessel (Freed *et al.*, 1998). In this system, constructs tumble in a fluid-filled annulus, enhancing nutrient transport while maintaining a low-shear environment, with long-term culture resulting in cartilage-like constructs with near-native material proper-

ties (Vunjak-Novakovic *et al.*, 1999). In addition to enhancing growth via improved nutrient transport, beneficial effects of direct application of physical forces on engineered articular cartilage constructs have been widely reported. For example, when a combination of hydrostatic pressure and perfusion was applied to chondrocyte-seeded polymer meshes, improved matrix deposition was observed (Carver and Heath, 1999). In other studies, dynamic deformational loading of constructs improved the biochemical and mechanical properties of constructs (Mauck *et al.*, 2000). Cyclical shear deformation of high-density scaffold-free chondrocyte cultures on a calcium phosphate scaffold improves properties as well (Waldman *et al.*, 2003). This applied mechanical environment may also interact synergistically with anabolic growth factors (Gooch *et al.*, 2001). As these systems become more advanced, the rate and quality of cartilaginous-tissue growth may be expedited and a functional tissue-engineered cartilage construct realized.

### MSCs and Cartilage Tissue Engineering

Although significant progress has been made in the production of engineered cartilage constructs with chondrocytes, several significant impediments exist that limit their clinical application. First, chondrocytes are present in limited supply and are often of an aged and/or diseased state in patients presenting with OA. While most tissue-engineering studies in the literature report on newborn- or juvenile-derived chondrocytes, a recent study has shown that aged chondrocytes are less able to form functional constructs in agarose culture (Tran-Khanh *et al.*, 2005). Finally, chondrocytes must be isolated from the joint tissue itself, a process that may further complicate an already damaged joint. One opportunity for overcoming such concerns is the use of adult MSCs. As described earlier, these cells are readily obtained from the adult bone marrow and other tissues and retain a multilineage potential. These cells are expandable in culture (Bruder *et al.*, 1997) and may be grown in sufficient numbers to populate engineered scaffolds.

### MSC Chondrogenesis Potential and Control

Control of chondrogenesis in MSCs is a complex and developing research area, with much of our understanding of the relevant molecules and processes stemming from a continuing elucidation of the events that control healthy cartilage homeostasis as well as cartilage formation in the developing limb. Elements including soluble factors such as growth factors, cytokines, hormones, various intracellular signaling pathways and transcription factors, environmental factors such as mechanical loading and oxygen levels, and seeding density all affect chondrogenic differentiation of MSCs.

The standard system of MSC chondrogenesis involves a three-dimensional culture of MSCs under the stimulation of a suitable chondrogenic stimulus. High-density cultures of pellet or micromass are frequently employed, reminiscent

of early chondrogenesis in development, where condensation of the early progenitor cells initiates the cascade of events leading to cartilage formation (Tuan *et al.*, 2004). In addition, MSCs are also seeded on various three-dimensional scaffolds to induce chondrogenesis. In this system, cell-seeding density, similar to what has been observed with chondrocytes, also affects the extent of chondrogenesis. For example, MSCs seeded at a higher density in agarose gels exhibited more cartilage-specific gene expression (Huang *et al.*, 2004b). MSCs that have undergone chondrogenic differentiation assume a chondrocyte-like phenotype characterized by increases in PG deposition and expression of aggrecan, COMP, and collagen type II (Barry *et al.*, 2001). Microarray analysis has shown that numerous other cartilage ECM elements increase in their expression as well (Sekiya *et al.*, 2002b).

Growth factors that have regulatory effects on MSCs include members of the TGF- $\beta$  superfamily, the IGFs, the FGFs, and the PDGFs. Among these growth factors, TGF- $\beta$ s, including TGF- $\beta$ 1, TGF- $\beta$ 2, and TGF- $\beta$ 3, as well as BMPs are the most potent inducers to promote chondrogenesis of MSCs (Fig. 55.3). For human MSCs, TGF- $\beta$ 2 and TGF- $\beta$ 3 were shown to be more active than TGF- $\beta$ 1 in promoting chondrogenesis (Barry *et al.*, 2001). BMPs, known for their involvement in cartilage formation, act alone or in concert with other growth factors to induce or enhance MSC chondrogenic differentiation. For example, BMP2, BMP4, or BMP6, combined with TGF- $\beta$ 3, induced the chondrogenic phenotype in cultured bone marrow derived hMSC pellets,

with BMP2 seemingly the most effective (Sekiya *et al.*, 2005). Other growth factors, such as IGF, FGF, and PDGF, are important signaling molecules that mediate chondrocyte physiology, rather than promoting chondrogenesis of MSCs, and therefore commonly work with TGF- $\beta$ s to promote chondrogenesis and enhance chondrocytic activities of differentiated MSCs. The promitotic activity of the FGFs has also been exploited for cell expansion purposes (Mastrogiacomo *et al.*, 2001). Interestingly, FGF2-supplemented hMSCs proliferated more rapidly and exhibited greater chondrogenic potential than untreated controls (Solchaga *et al.*, 2005). Wnt proteins have recently been implicated in the progression of rheumatoid arthritis and OA (Loughlin *et al.*, 2004). Canonical Wnt signaling has been shown to enhance MSC differentiation (Yano *et al.*, 2005), and Wnt signaling in chondrogenesis has been shown to cross-talk with TGF- $\beta$  signaling (L. Fischer *et al.*, 2002; Tuli *et al.*, 2003; Zhou *et al.*, 2004).

Growth factors act on cells and induce various intracellular signaling pathways to coordinate transcription factors and change cellular phenotype. One of the most important molecules intrinsic to the assumption of the cartilaginous phenotype is the transcription factor sox9. The role of sox9 in cartilage formation was first observed in condensations in the developing mouse limb, and its presence is thought to be required for cartilage formation (Bi *et al.*, 1999). In human bone marrow derived MSCs, exogenous expression of sox9 led to increased PG deposition (Tsuchiya *et al.*, 2003).

**FIG. 55.3.** Chondrogenic differentiation of mesenchymal stem cells: effect of TGF- $\beta$ 3. Time-dependent increase in Alcian blue staining of matrix sulfated proteoglycan deposition by bovine MSCs maintained in three-dimensional agarose culture ( $20 \times 10^6$  cells/mL) in a chemically defined chondrogenic medium with (top) and without (bottom) supplementation of 10 ng/mL TGF- $\beta$ 3. Bar, 100  $\mu$ m.

In addition to sox9, other *cis* and *trans* acting factors and intracellular signaling pathways have been shown to modulate differentiation toward a chondrogenic phenotype. Factors such as AP2- $\alpha$  have been shown to negatively regulate chondrogenesis in ATDC5 cells, a prechondrogenic cell line, that have been induced with either insulin or TGF- $\beta$  (Huang *et al.*, 2004d). Intracellular signaling cascades, particularly those involving the MAP kinases, p38 and ERK-1, are activated by TGF- $\beta$ 1 during cartilage-specific gene expression in MSCs, and specific inhibitors of these pathways block or limit chondrogenesis (Tuli *et al.*, 2003). In MSCs, it was also demonstrated that TGF- $\beta$ 1 and p38 MAP kinase signaling pathways converge on AP2 DNA binding during chondrogenesis, suggesting that one mechanism by which these signaling cascades may induce the cartilage phenotype is through interruption of the transcriptional repression exerted by AP2 (Tuli *et al.*, 2002). Taken together, these findings in MSCs suggest a complex interplay of extracellular growth factor molecules, signal transduction to the nucleus, and coordinated control of transcription factors for the induction of the chondrogenic phenotype. The current challenge in finding the most efficient growth factor(s) for MSC chondrogenesis is that the regulatory effects of signal molecules are dependent on property, dose, and timing of the molecules administered to the cells. That may explain some of the contradictory results regarding the effects of specific growth factors on chondrogenesis.

### Cartilage Tissue Engineering with MSCs

The use of MSCs for cartilage regeneration and tissue engineering has shown enormous potential and initial success. Of note, one current surgical strategy for enhancing the repair of cartilage defects is via microfracturing of the subchondral bone. This technique provides entrance for marrow elements, including MSCs, to the wound site, and has been shown to generate an enhanced, albeit fibrous, repair response. MSCs have been used as cellular therapeutics directly, via direct injection into the joint space (with and without a carrier matrix) in an undifferentiated state (Murphy *et al.*, 2003) and after differentiation down a cartilage lineage *in vitro* (Yoo *et al.*, 2000). These cells may be further transduced to express morphogenetic proteins that drive their own chondrogenesis after implantation (Palmer *et al.*, 2005).

In the context of tissue engineering, MSCs have been shown to undergo chondrogenesis in a variety of three-dimensional scaffolds. In one of the first studies of its kind, avian bone marrow stromal cells were shown to undergo chondrogenesis and osteogenesis in nonwoven PGA scaffolds with culture in inductive media (Martin *et al.*, 1998). Since then, positive chondrogenesis has been demonstrated in such scaffolds as agarose (Awad *et al.*, 2004; Huang *et al.*, 2004b), alginate (Awad *et al.*, 2004), fibrin (Worster *et al.*, 2001), gelatin (Awad *et al.*, 2004), collagen types I and II hydrogels (Bosnakovski *et al.*, 2006), polyethylene oxide

(Williams *et al.*, 2003), silk (Meinel *et al.*, 2004), and PLA (Noth *et al.*, 2002) as well as on biodegradable nanofibers (Li *et al.*, 2005b) (Table 55.3). Polymeric nanofibrous scaffolds composed of ultrafine fibers at the nanometer-level scale, by virtue of structural similarity to natural ECM, represent promising structures for cartilage tissue engineering. Recent findings indicate that the biological activities of chondrocytes (Li *et al.*, 2003) and mesenchymal stem cells (Li *et al.*, 2005b) are crucially dependent on the dimensionality of the extracellular scaffolds and that nanofibrous scaffold may be a biologically preferred scaffold/substrate for proliferation and phenotype maintenance of chondrocytes (Fig. 55.4) and chondrogenic differentiation of mesenchymal stem cells. In addition, for cartilage-tissue engineering, both *in vitro* and *in vivo* results have shown that nanofibrous scaffolds support chondrogenic differentiation of MSCs.

One remaining caveat in the MSC-based engineered cartilage tissue is the functional mechanical properties of the cartilaginous matrix formed. Recent studies have shown that MSCs in agarose and alginate hydrogels do undergo chondrogenesis and do deposit ECM with increasing mechanical properties with time in culture (Mauck *et al.*, 2006). However, the mechanical properties of the forming matrix were inferior to those of donor-matched chondrocytes similarly maintained. These findings suggest that, as was done with primary chondrocytes, a complete optimization regimen may be required to generate MSC-laden constructs that possess functional properties similar to those of the native tissue.

One such approach is to consider the role of mechanical signals in this process. Recent studies have shown that even fully differentiated tissues alter their phenotype with changes in the mechanical environment. Functional tissue engineering is likely to be dependent on similar physical forces that regulate development and maintenance of cellular phenotype. Indeed, some of the very signals that cause differentiation may be used to optimize construct growth. To date, few studies have directly examined mechanically induced differentiation in a tissue-engineering environment. For example, tensile stretching increased ligament differentiation of MSCs in collagen (Altman *et al.*, 2002), while cyclic substrate strain enhanced osteogenesis (Simmons *et al.*, 2003). Both static and dynamic loading have been shown to increase the chondrogenesis of limb bud cells in collagen and agarose (Elder *et al.*, 2001; Takahashi *et al.*, 1998), depending on the frequency and duration. Fluid pressure has recently been shown to enhance chondrogenesis of pellet cultures (Angele *et al.*, 2003), and studies in agarose hydrogels (Huang *et al.*, 2004a) have demonstrated enhanced MSC chondrogenesis with dynamic deformational loading. These findings motivate a continued exploration in the role of the mechanical loading environment in both inducing differentiation as well as enhancing subsequent construct maturation.

## Bone Tissue Engineering

Bone has a vigorous potential to regenerate itself after damage; however, the efficacious repair for large bone defects resulting from resection or trauma or nonunion fractures still requires the implantation of bone grafts. Natural bone grafts possessing excellent osteoconduction and mechanical stability have been used extensively in clinical settings; depending on the relationship between the donor and the recipient, bone grafts are categorized into autografts, allografts, and xenografts. Autografts, considered the gold standard for bone implantation, have the advantage of immunocompatibility over allografts and xenografts. However, problems such as donor site morbidity, risk of infection, and the availability of bone tissue of the correct size and shape limit the use of autografts in orthopedic applications.

Two hundred thousand surgical cases of bone-grafting procedures are performed annually, and thus the demand for bone grafts continues to rise and is expected to be even greater over the next decade as the population ages. One possible remedy for the shortage of bone grafts is a functional tissue-engineered bone graft. Both *in vivo* and *in vitro* tissue engineering approaches are employed for bone-tissue engineering using MSCs. The primary difference between these two approaches is the additional step of allowing the *ex vivo* formation of mature bone grafts, which provides a better control over the growth environment of bone tissue and could also ensure the production of mature, functional bone grafts before surgical implantation. However, this process requires longer times and skillful techniques to produce tissue-engineered bone grafts. In contrast, because the *in vivo* approach is more direct, development of this strategy is ahead of that of the other, and it has already been used in clinical applications.

MSCs are an attractive cell type for bone tissue engineering due to their potentials of extensive expansion and default osteogenic differentiation. Successful and complete osteogenic differentiation of MSCs is imperative for bone formation and still remains a challenge in bone-tissue engineering. Although it has been well known that the signals driving MSCs into osteogenic differentiation include biochemical cues from growth factors/cytokines and physical contacts from cell-cell or cell-matrix interactions, the molecular mechanisms regulating osteogenic differentiation of MSCs have yet to be fully described.

Normal or genetically modified MSCs as therapeutic agents injected into recipients have successfully induced ectopic bone formation. However, the injected cells require three-dimensional biomaterial scaffolds to secure them at the implantation site, provide physical protection, and maintain and direct tissue shape. In MSC based bone tissue engineering, various biomaterial scaffolds have been evaluated for their potential as cell carriers. These scaffolds may be made from natural (Chen *et al.*, 2002) or synthetic (E. M. Fischer *et al.*, 2003; Partridge *et al.*, 2002) materials that have

been fashioned into structures with different shapes and sizes. In general, natural polymers, such as collagens, contain bioactive domains favorable for biological activities involved in tissue regeneration, whereas synthetic polymers, such as poly( $\alpha$ -hydroxyesters), feature controllable material properties that can approximate the physical properties of native tissue. Among the materials that have been used in bone tissue engineering, hydroxyapatite (HA) and their derivatives, such as  $\beta$ -tricalcium phosphate ( $\beta$ -TCP), are the most common scaffold materials for osteogenic induction of MSCs. Bioabsorbable TCP-based scaffolds, compared to HA-based ones, showed comparable results on ectopic bone formation (Boo *et al.*, 2002). Moreover, both synthetic ceramics support osteogenic differentiation more efficaciously than demineralized bone matrix (Kasten *et al.*, 2005). To improve the affinity of osteoconductive ceramics for cells, HA has been coated with bioactive peptides (Sawyer *et al.*, 2005) or proteins (Yang *et al.*, 2005), to enhance MSC attachment and osteogenic differentiation. Furthermore, it is well known that the chemistry and architecture of scaffolds are important factors in promoting MSC-based bone formation. Recently, a novel electrospun nanofibrous scaffold, morphologically similar to native ECM, has been applied to bone-tissue engineering. The ultrafine ECM-biomimetic nanofibers favorably supported osteogenic differentiation of MSCs *in vitro* (Li *et al.*, 2005a) and *in vivo* (Shin *et al.*, 2004).

A recent preferred trend is to combine multiple materials to produce a composite with the properties from each of the composed materials. Composite scaffolds are expected to be physically and biologically superior to single-material-based scaffolds, for the properties of a composite may be programmatically varied by mixing different materials in various ratios. Both the composition and the relative ratio of the constituent materials can affect bone formation. HA has been used as a primary material combined with another material, such as TCP (Shi *et al.*, 2005), PLGA (Turhani *et al.*, 2005), and chitin (Huang *et al.*, 2004c), to produce various composite scaffolds. It was reported that scaffolds with different ratios of HA/TCP loaded with MSCs showed different extents of bone formation *in vivo*. Composites in which the HA/TCP ratio was designed to coordinate scaffold degradation with tissue deposition seemed optimal in promoting the greatest ectopic bone formation (Arinze *et al.*, 2005).

Growth factors, cytokines, and other nonproteinaceous chemical factors are critical for osteogenic differentiation of MSCs, as discussed earlier. To augment bone formation successfully, it is necessary to continuously introduce osteoinductive molecules, most of which have a short half-life, into the cell culture or the defect site. One strategy for enhancing bone formation is to use biomaterial scaffolds both as a cell carrier as well as a reservoir for the release of growth factors in a controllable manner. BMP2 is the most efficacious growth factor among the BMP family members

and has been incorporated in various forms of biomaterial scaffolds to induce osteogenesis in *ex vivo* cultures (Huang *et al.*, 2004c) or to stimulate bone formation in *in vivo* models (Saito *et al.*, 2001).

Bioreactor systems, such as spinner flasks, rotating-wall vessels, and perfusion chambers, have also been demonstrated to be useful tools for enhancing bone formation of MSC-laden scaffolds *in vitro*. Such systems more closely resemble the *in vivo* environment of cells by providing a dynamic culture system that improves mass transport. Some bioreactor designs also apply mechanical loading to the cultured bone constructs, actively inducing osteoblast maturation and stimulating bone matrix production. These MSC-laden constructs with mechanical loading in culture became biologically more mature and mechanically stronger, compared to those without mechanical loading (Mauney *et al.*, 2004).

### Osteochondral Tissue Engineering

Severe joint defects often extend to damage or destruction of subchondral bone, leading to associated pain and mechanical instability of the joint. It is well known that the body attempts a spontaneous repair of osteochondral lesions that penetrate the subchondral bone by activating the healing mechanism mediated by MSCs in the exposed bone marrow. Clinically accepted treatments, such as microfracture, apply the same concept to encourage healing and regeneration of the lost cartilage. However, the density of MSCs released by the physical destruction of subchondral bone is low and often not enough for efficient repair. Instead of mechanically strong hyaline cartilage, the lesion is usually repaired by fibrocartilage that erodes over a short time period. In addition, due to the removal of subchondral bone, increased mechanical instability of the lesion site makes the repair even more difficult. Clinical results show that, even for a partial-thickness cartilage defect, there are beneficial effects in exposing subchondral bone by drilling as well as the incorporation of a bone layer as an anchor to integrate with host tissue securely. Therefore osteochondral grafts or plugs are used clinically in the treatment of both chondral and osteochondral defects.

A tissue-engineered osteochondral graft, composed of both cartilage and bone components, is a promising alternative to the use of autologous osteochondral grafts. The engineered construct is more controllable in size and shape, and donor site morbidity experienced when grafts are harvested for mosaicplasty procedures is eliminated. For osteochondral tissue engineering, a number of three-dimensional biomaterial scaffolds have been developed, with the aim of optimizing MSC attachment, proliferation, and osteogenic/chondrogenic differentiation. Such scaffolds, including hyaluronan (Radice *et al.*, 2000) and hyaluronan-gelatin (Angele *et al.*, 1999), can be used as delivery vehicles *in vivo* for a large number of *ex vivo*-expanded MSCs to the lesion site while providing physical

protection to the resident cells. In this approach, although MSCs are retained locally at the osteochondral lesion for the repair, the actual regeneration of tissue is unpredictable and depends primarily on the host tissue. A more sophisticated approach for osteochondral tissue engineering is to take advantage of the multidifferentiation potential of MSCs to fabricate an osteochondral composite graft *in vitro* or *ex vivo* before implantation. In contrast to using merely three-dimensional biomaterial scaffolds as delivery vehicles without *in vitro* tissue preformation, this approach can produce a functional osteochondral graft that is biologically similar to the native host tissue. Angele *et al.* (1999) have shown that the repair of osteochondral lesion, using the precultured osteochondral graft, is indeed more effective.

Osteochondral grafts are single-unit biphasic composite materials consisting of two tissues with different properties, with cartilage on the top of bone, and as such have been technically challenging to engineer. Chondrogenesis and osteogenesis of MSCs require different physical and biochemical cues from matrices and soluble growth factors/cytokines, respectively. A commonly used approach is to fabricate cartilage and bone independently before integrating them together using sutures or glues (Gao *et al.*, 2001; Schaefer *et al.*, 2000). In one approach, MSCs loaded into a hyaluronan or a TCP ceramic scaffold were separately induced to undergo chondrogenic or osteogenic differentiation. Then the two components were integrated together with fibrin sealant, becoming a single unit of an osteochondral construct (Gao *et al.*, 2001; Schaefer *et al.*, 2000). One drawback with this method is the less-than-optimal integration between the chondral and osteo constructs; poor integration leads to discontinuous cell distribution at the interface and/or the possibility of eventual separation of the two components. Several groups have reported different alternatives to solve the problem of discontinuous interface. In one approach, MSCs after *in vitro* chondrogenic or osteogenic differentiation were loaded into two separate polyethylene glycol (PEG) hydrogel layers and the cell-loaded PEG gels were then photopolymerized together. Since the two components were combined before gel solidification, the osteochondral construct exhibited a less defined gap line (Alhadlaq and Mao, 2005). Another approach was to apply a press-coating process (Noth *et al.*, 2002) to fabricate osteochondral constructs. A PLA scaffold was press-coated with a high density pellet of MSCs previously induced in chondrogenic culture and subsequently seeded with preosteogenically differentiated MSCs at the other end of the scaffold. Macroscopically, the osteochondral composite consisted of a cartilage-like layer adherent to and overlying a dense bonelike component (Tuli *et al.*, 2004). Since both cartilage and bone were produced in a single unit, there existed no gap between the two tissues; instead, an interface resembling the native osteochondral junction was observed.

The ideal scenario for the fabrication of biphasic osteochondral constructs would be to differentiate MSCs cultured

in a single-unit scaffold into chondrocytes on the top and osteoblasts on the bottom. To this end, the biomaterial scaffold should chemically and structurally support both chondrogenesis and osteogenesis. Novel nanofibrous scaffolds morphologically resembling natural ECMs have been shown successfully to support chondro- and osteogenesis of MSCs *in vitro* (Li *et al.*, 2005a). Another need for achieving this goal is a culture system in which an MSC-laden construct can differentiate into cartilage and bone simultaneously. A double-chamber bioreactor with a unique two-compartment design allowing the storage of different media was used to culture osteochondral constructs (C. H. Chang *et al.*, 2004). With this double-chamber bioreactor, it would be feasible to engineer an autologous osteochondral graft using MSCs by means of a nanofibrous scaffold.

### Engineering Other Skeletal Tissues with MSCs

In addition to their clear roles in engineering bone and cartilaginous tissues, MSCs may be readily used for the repair of numerous other musculoskeletal tissues. This is partially predicated on the belief that endogenous tissue repair of these tissues may be driven by progenitor cells located within or those that migrate into injury sites, proliferate, and deposit new matrix. Indeed, an increasing number of musculoskeletal tissues have been found to harbor cells that retain some multipotential characteristics, including articular cartilage, meniscus, trabecular bone, synovium, heart and skeletal muscle, and periodontal ligaments (Table 55.1). These findings suggest a wide distribution of these cells and consequently the potential for effecting repair of specific tissues via their exogenous application. If successful, such cell-based tissue engineering therapies would rectify what are otherwise untreatable and progressively debilitating disorders.

Tendon and ligament tissue engineering was one of the first areas in which MSCs have found application. In early studies, it was observed that rabbit MSCs contract collagen type I carrier gels and that the delivery of these constructs to patellar and Achilles tendon defects improved the biomechanical properties of the repair tissue as compared to acellular controls (Young *et al.*, 1998). Newly emerging silk scaffolds that have been modified with arginine-glycine-aspartic acid moieties and/or formed into nanofibrous scaffolds may also prove useful for tendon/ligament-tissue engineering with MSCs (Jin *et al.*, 2004). Recent studies, applying tensional and torsional mechanical stimulations to MSC-seeded collagen gels *in vitro*, have shown enhanced fibrous differentiation (Altman *et al.*, 2002). These studies suggest a role for MSCs in accelerating the repair of tendon and ligament defects that may be modulated by the mechanical loading environment.

Another tissue in which exogenous MSC application has been used to effect repair is the fibrocartilaginous knee meniscus. It has been reported that intraarticular injection of MSCs (absent a tissue-engineering delivery vehicle) can

have an ameliorating effect on articular cartilage and meniscus degeneration. Injection of MSCs in hyaluronan in an anterior cruciate ligament resection/medial meniscectomy model led to some regeneration of the meniscus and protection of the underlying cartilage (Murphy *et al.*, 2003), with GFP-labeled MSCs colonizing the healing meniscus. Alternatively, direct delivery of MSCs to meniscal defects within a fibrin clot led to the maintenance of cells in the defect for up to eight weeks after implantation (Izuta *et al.*, 2005). Clearly, MSCs can play a role in the reparative process of the meniscus, although the mode of their administration and the nature of the carrier materials require further optimization.

In addition to these purely fibrous structures, MSC therapy is being widely investigated for treatment of other musculoskeletal tissues, including skeletal and cardiac muscle and intervertebral disc. Taken together, these findings suggest that MSCs will find wide application in the treatment of a number of different musculoskeletal disorders, greatly expanding the realm of regenerative medicine and ultimately enhancing the quality of human life.

### Gene Therapy in Musculoskeletal-Tissue Engineering

Gene therapy is a promising technique for disease treatment, in which the genetically modified cells are transferred into or generated within individuals for therapeutic purposes. The cells with modified genes can be programmed to differentiate into desired cells or produce proteins needed for tissue repair. Although some safety issues still remain, a likely future scenario is the merging of gene therapy, cell therapy, and tissue engineering for the treatment of musculoskeletal diseases.

Two strategies are currently used in gene therapy, viral transduction and nonviral transfection, and both strategies can be conducted *in vivo* and *ex vivo*. *In vivo* gene therapy is simple but often lacks tracking of the gene-modified cells and target site specificity. An attractive alternative is to combine gene therapy with a tissue-engineering approach to transduce or transfect cells of interest *ex vivo* and then to use a carrier to deliver these genetically modified cells to the target site. This approach offers the advantages of flexibility of target cell type and retaining of gene-modified cells at the site of interest. Gene transduction using viral vectors, such as retrovirus, adenovirus, and lentivirus, effectively modifies the host chromosome but raises concerns on mutagenesis and the immune response. In contrast, the nonviral approach is safer, but the efficiency of transfection is lower. More research efforts are needed to overcome the limitations associated with each approach. The ultimate goal is to develop a simple, safe, and effective approach to transfer genes into the cell of interest.

Currently, the most frequently applied example of gene therapy in bone tissue engineering is the transduction/transfection of interested cells with BMP genes. BMPs play

important roles in the regulation of osteogenic differentiation of MSCs and the production of bone matrix during bone formation. To overcome the short half-life limit of growth factors, MSCs are transduced or transfected with BMP genes for the continuous expression of the required BMPs *in vitro* and *in vivo*. The BMP2-transduced MSCs were induced to differentiate into osteoblasts producing bone matrix and to synthesize BMP2, attracting the host cells to migrate and differentiate. Compared to control MSCs, the BMP2-producing MSCs effectively enhance bone formation, even at large defect sites like segmental femoral defects (Lieberman *et al.*, 1999). Similar results have also been reported when BMP2- or BMP4-transduced MSCs were delivered to bone defects using different biomaterial scaffolds, such as demineralized bone matrix (Lieberman *et al.*, 1999) and gelatin (Gysin *et al.*, 2002). Runx2 is an early transcription factor regulating osteoblast differentiation. One recent study has shown that Runx2-modified MSCs cultured in three-dimensional polymeric scaffolds successfully created a bone construct with significantly up-regulated osteoblast differentiation and mineralization (Byers *et al.*, 2004). Other osteogenic transcription factors, such as Osterix, and Foxc1 have also been shown to promote MSC osteogenic differentiation.

The potential benefits of cartilage repair using gene therapy are also gaining recognition. For example, BMP7-transduced MSCs delivered by PGA scaffolds successfully regenerated cartilage, whereas the control nontransduced group did poorly (Mason *et al.*, 2000), and BMP4 transduction induced chondrogenesis and enhanced cartilage repair (Kuroda *et al.*, 2006). The level of chondrogenesis in MSCs transduced with various growth factors was dependent on the level of expression of the exogenous genes (Palmer *et al.*, 2005).

## IV. CONCLUSIONS AND FUTURE PERSPECTIVES

MSCs, isolated from various tissues, can be maintained in culture and self renew to yield a large number of cells in an undifferentiated stage and then, under appropriate conditions, to differentiate into cells of various mesenchymal lineages, including cell types of the musculoskeletal tissues. Due to their ease of isolation, their capacity for

undergoing *in vitro* proliferation to achieve a cell number large enough for cell therapy, their ability to undergo lineage-specific differentiation into musculoskeletal cells, and their potential immunomodulatory advantages, MSCs present significant potential in musculoskeletal tissue engineering, which promises to bring hope to patients and surgeons alike for the generation of functional tissue substitutes. As discussed in this chapter, MSCs have been used in tissue engineering of a number of musculoskeletal tissues, including cartilage, bone, osteochondral constructs, ligament, and tendon, with varying degrees of success. Currently, tissue-engineered constructs have not been readily accepted for clinical use to treat skeletal tissue defects. There clearly is a need for further research that combines the concerted efforts of biologists as well as engineers and clinicians. Critical to the success of these approaches is a better understanding of MSC biology, which still poses great challenges. So far, there has not been a marker that can be used unequivocally to identify and prospectively select MSCs from various tissues. The factors that regulate phenotype transition, i.e., uncommitted vs. differentiated phenotype, remain to be identified and studied. Additionally, the various growth factors, signaling pathways, and transcription factors that can influence MSCs to differentiate completely and stably into a desirable lineage require further elucidation. Further complicating the matter is the heterogeneity and differences among various tissue sources of MSCs. Despite our limited understanding of MSC biology, the use of MSCs in musculoskeletal tissue engineering has shown great promise. Future efforts in this area should include the fabrication of optimized scaffolds, systematic studies of the interplay of MSC, scaffold and environmental factors, and the development of quantitative outcome measurements for tissue-engineered constructs. *In vivo* testing of the engineered construct serves as the gold standard for the long-term survival of the constructs and warrants much greater attention. However, the immunosuppressive and anti-inflammatory effects of MSCs offer encouragement in their use in allogeneic transplantation in the inflammatory environment of an injury site. With further research and development, the use of MSCs in tissue engineering is expected to bring to fruition a tissue substitute that is functionally suitable for implantation to improve the quality of life of patients with debilitating musculoskeletal injuries.

## V. ACKNOWLEDGMENT

This work is supported by the NIAMS Intramural Research Program (NIH Z01 41113).

### I. INTRODUCTION

Research in bone regeneration truly took off in the 1960s when Burwell *et al.* confirmed bone marrow's osteogenicity and Urist discovered bone morphogens. Scientific advances in bone-tissue engineering was thus achieved through both in-depth understanding of bone cell biology as well as progress in the isolation, purification, and commercial-scale generation of bone-specific growth factors. Two schools of thought related to the engineering of bone tissue evolved from these findings: Bone repair was accomplished, on one hand, through the use of cell-based therapies; while, on the other hand, bone repair was addressed using an increasingly diverse palette of growth factors. In this chapter, currently available approaches as well as ongoing research paths to engineer bone tissue *in vivo* are described.

#### **Bone Engineering – Paradigm Shift from *In Vitro* to *In Vivo* Tissue Growth**

The concept of regenerating bone tissue for orthopedic and spinal applications has spurred long-term research efforts and, despite significant progress, is still facing a number of clinical challenges. Autologous iliac crest bone graft (ICBG) is considered the gold standard to repair bone, despite its limited supply and the morbidities associated with harvesting this tissue, such as infections, seromas, hematomas, herniation, vascular and neurologic injuries, and iliac wing fractures (Arrington *et al.*, 1996). Although severe complications from harvesting autograft are rare, donor site pain is reported in the literature in ranges of

25–49%, with 19–27% of patients experiencing chronic site pain two years postoperatively (Fernyhough *et al.*, 1992; Heary *et al.*, 2002). Unfortunately, these morbidities are also found to be unrelated to surgical approach or patient demographics, such as age and gender, thus making it impossible for surgeons to predict or prevent pain within their patient population (A. R. Gupta *et al.*, 2001). Significant research therefore focuses on developing new bone regeneration options that would alleviate the need for autograft harvesting.

In the early 1990s, advances in bone cell biology, combined with expertise in material sciences, fueled the notion of engineering bone chips in petri dishes. The initial concept consisted of taking cells from a patient, seeding them *in vitro* to create bone chips that would look and feel very much like autologous bone chips, and then reimplanting them in the patient as needed. This approach was based on the idea that cells harvested from a patient's bone marrow would generate unlimited volumes of tissue, which would also be devoid of risks of rejection or disease transmission. These concepts were in part confirmed by advances in stem cell biology that demonstrated the potential of bone marrow aspirates to grow in culture and to generate significant numbers of stem cells (Bruder *et al.*, 1997).

While this design seemed to address some of the key limitations related to the use of autograft, it brought along its own challenges. From a purely logistical perspective, the *in vitro* phase of the tissue-engineering design was riddled with complications, for it would require a long and

potentially complex regulatory path to market, carried risks of culture contamination, and was not easily optimized for large-scale applications. The economics of this approach could also prove particularly unfavorable since the majority of cases seen by orthopedic surgeries are known to respond with excellent clinical outcomes while employing fairly basic technology; the market for a true “tissue-engineered” approach would therefore be limited to a relatively small number of high-risk patients.

In addition to these logistical and financial considerations, parallel progress in medical devices, pharmacology, and cell biology further modified the bone regeneration landscape with the development of new point-of-care cell concentration devices, recombinant growth factor technologies, or allogeneic stem cell banks. The concept of an *in vitro* engineered bone chip was thus made obsolete. Instead, current approaches focus on creating the right biological environment *in vivo* to promote bone healing.

### Two Parallel Approaches to Bone Regeneration

A decade of bone-tissue-engineering endeavors and more than 50 years of intense bone biology research highlighted the three key elements required to create a biological environment suitable for bone formation: (1) presence of matrix material for cell attachment and proliferation (osteoconduction); (2) critical mass of osteogenic cells (stem cells or progenitors that are capable of forming new bone tissue); and (3) biological factors to promote chemotaxis, cell proliferation, and differentiation. Currently, two parallel paths are being explored to create this optimized bone bed. The first approach focuses primarily on the delivery of a critical mass of osteoprogenitor cells to the repair site — and relies on autologous growth factors present in the body in physiological concentrations — to form bone. The second approach is based on the delivery of high doses of biological factors — and relies on the availability and responsiveness of autologous stem cells in the body — to achieve bone formation.

### Cell-Based Therapies

The clinical use of cell-based therapies to aid in bone regeneration dates back to the 1940s, when the first reports were published on the use of bone marrow injections as a source of stem cells into nonunions (Phemister, 1947). In the 1960s, Burwell (1964) further defined the bone regeneration potential of the iliac crest autograft as a function of the crest’s marrow content. Since that time, while plain bone marrow injections are still in some cases the therapeutic option du jour, scientific developments provided health care professionals with (1) optimized matrices to attach and maintain bone marrow cells; (2) point-of-care bone marrow cell concentration methods; and (3) allogeneic, culture-expanded stem cell concentrates. Review of these major approaches and published results are described further in this chapter.

### Growth Factor-Based Therapies

Concurrent with Burwell’s bone marrow research was Urist’s first description of bone morphogenetic proteins (BMPs), which were later characterized as a family of growth factors present in the bone matrix and capable of inducing local progenitor cells into osteoblastic development (Urist, 1965; Lindholm *et al.*, 1982). These findings were followed by hundreds of publications describing the role of BMPs, and more specifically BMP-2, in bone formation. A recombinant human form of BMP-2 (rhBMP-2) was thus bioengineered to be mass-produced and was the first bone morphogen to enter the clinical market, in 2003. A review of rhBMP-2 and other growth factors on the market or in development for bone repair is provided in this chapter.

## II. CELL-BASED APPROACH TO BONE-TISSUE ENGINEERING

As just defined, cell-based therapies are based on the delivery of cells and rely on the presence of autologous growth factors for biological stimulation. More specifically, cells required for cell-based bone regeneration therapies are so-called osteogenic cells. Osteogenic cells include all cells that are or will differentiate into osteoblasts capable of forming bone. Currently, only autogenic and allogeneic osteogenic cells are used clinically or evaluated for use. These human cells can be harvested from two key sources: (1) differentiated bone tissue, and (2) nonbony tissues containing mesenchymal stem cells (MSCs); such tissues include bone marrow as well as other connective tissues (Bruder and Caplan, 2000).

Differentiated bone tissues have recently been described as potential sources of osteogenic cells. These tissues consisted of mature bone fragments, obtained as debris from reaming procedures (Wenisch *et al.*, 2005). Bone fragments did not contain any bone marrow, and thus the osteogenicity of the bone fragments was described as specifically due to bone-lining cells. This source of osteogenic cells has not been widely investigated yet and thus will not be described further in this chapter.

The key sources for osteogenic cells therefore remains nonbony connective tissues and bone marrow. Various differentiated connective tissues have been shown to contain osteogenic cells that could form bone in specific culture conditions (Zuk *et al.*, 2002) and are currently being investigated for potential use in bone regeneration. Bone marrow, on the other hand, has a long track record of preclinical and clinical efficacy for bone repair and remains the most easily accessible and richest source of MSCs.

### Current Therapies

#### Use of Bone Marrow as a Source of Stem Cells

Of all human tissues, bone marrow was found to be particularly advantageous from a cell-sourcing perspective, for it can be obtained from the iliac crest using a

**FIG. 56.1.** Photographs of a hydroxyapatite-coated collagen type I sponge (HEALOS®) prior to use (a) and soaked with autologous bone marrow (b). Retention of bone marrow–derived cells on the HEALOS strips was observed by scanning electron microscopy (c).

noninvasive procedure with a simple needle aspiration. More importantly, it is self-renewing and was found to regenerate its own nucleated cellular content within 90 days (Stroncek *et al.*, 1991). Bone marrow has therefore been extensively evaluated, from a cell biology perspective as well as from an overall efficacy point of view, in culture dishes as well as in animal and clinical cases.

#### Cellular Content of Bone Marrow

Bone marrow was shown in the mid-1960s to contain two different stem cell systems: hematopoietic and mesenchymal (Friedenstein *et al.*, 1968). The hematopoietic system was shown to ensure long-term formation and renewal of all hematopoietic tissues and contains cell types at all stages of hematopoietic cell maturation. Hematopoietic stem cells (HSCs) were also isolated from the marrow and shown to survive throughout life (Quesenberry *et al.*, 2005). The mesenchymal system was found to be responsible for the long-term formation and renewal of the “fibroblastic” stromal cells, which were involved in “mesenchymal” tissue formation, including bone, cartilage, muscle, ligament, and adipose tissue, as well as marrow stroma. The mesenchymal and hematopoietic systems were also found to be interdependent, because cytokines from mesenchymal stem cells could affect hematopoietic cell differentiation, and vice versa (Kuznetsov *et al.*, 1997).

Recently, a third type of precursor cell was identified within bone marrow: the “side population” (SP); these cells are defined by their ability to regenerate the hematopoietic compartment as well as to differentiate into osteoblasts through a mesenchymal intermediate (Olmsted-Davis *et al.*, 2002).

While bone marrow’s cellular content was fairly extensively analyzed, little research was done on the plasma content of bone marrow. Thus, the noncellular phase of

bone marrow is still mostly undefined. However, bone marrow, with its diverse cellularity and its mostly unknown plasma content, has been tested extensively *in vivo*, in many animal models as well as in clinical cases.

#### In Vivo Evidence of Bone Marrow Osteogenicity: Preclinical Data

Bone marrow research *in vivo* has been strongly correlated with biomaterial research, for it was demonstrated early on that osteogenic cells required adequate surfaces for growth and proliferation. Ohgushi *et al.* (1989) utilized a porous three-dimensional hydroxyapatite carrier to demonstrate that bone marrow cells could heal critical-sized defects in rats. In addition, Tiedeman *et al.* (1991) used bone marrow aspirate on demineralized bone matrices to heal critical-sized tibial defects in dogs. Novel composite carriers that combine collagen and hydroxyapatite (HEALOS®) were also shown effectively to regenerate bone when combined with autologous bone marrow (Fig. 56.1). In this study, Tay *et al.* (1998) used a rabbit posterolateral fusion model to evaluate the effectiveness of bone marrow with or without heparin. Bone marrow on the carrier was found comparable to autograft.

In all published research, bone marrow osteogenicity was found to be critical to ensure efficacy. Poorly cellular bone marrow typically did not result in bone formation, while highly cellular bone marrow was found to be efficacious. An example of this concept was brought forward by two studies published in 2005 (Kraiwananapong *et al.*, 2005; Minamide *et al.*, 2005). Both Kraiwananapong and Minamide replicated the evaluation performed by Tay *et al.* in 1998, using bone marrow sources with lower cellularity. Tay *et al.* used bone marrow at 238 million cells/mL and observed healing in all cases. Kraiwananapong utilized bone marrow at 30 million cells/mL and did not observe any

healing. Minamide investigated two different cell concentrations, 1 million cells/mL as well as 100 million cells/mL. No healing was observed at 1 million cells/mL, while healing equivalent to autograft was observed at 100 million cells/mL, indicating a minimum cell mass requirement for efficacy.

This finding was supported by Andersen *et al.* (2003), who evaluated the relationship between the number of osteoblasts in an iliac crest bone graft and the resulting fusion mass in a posterolateral mini-pig-fusion model. The study found a statistically significant correlation between the number of cells implanted and successful fusion.

#### *In Vivo Evidence of Bone Marrow Osteogenicity: Clinical Data*

While no long-term, multicenter, prospective, randomized, blinded clinical studies have been completed to evaluate the efficacy of bone marrow vs. autograft, multiple clinical reports have described bone marrow for use in bone healing. Salama and Weissman (1978) published a preliminary report on 28 patients undergoing long-bone repair under conditions covering a wide range of indications. Autologous bone marrow aspirates were used in all cases and provided very satisfactory results. Connolly *et al.* (1991) described a technique to inject bone marrow directly into bone grafting sites, thereby alleviating the need for open surgery. Comparing healing patterns in 100 patients, the study reported an 80% healing rate following marrow grafting. In a clinical study for a collagen–calcium phosphate graft material (Collagraft®), Chapman *et al.* (1997) described the efficacy of bone marrow with the carrier in the treatment of long-bone fractures. No significant difference between the autograft and the bone marrow carrier groups was observed. In a more challenging clinical application, Garg *et al.* (1993) reported the use of percutaneous autogenous bone marrow grafting in 20 cases of nonunited fracture. After five months, 17 cases progressed to healing. Delayed union and nonunion cases were also treated with bone marrow by Sim *et al.* (1993), who described 11 cases that healed within a median time of 10 weeks following injection of bone marrow.

Bone marrow with allograft was used in a variety of pediatric cases, including cysts, fibromas, long-bone nonunions, and tibia-lengthening procedures (Wientroub *et al.*, 1989). In this study, all cases showed good new bone formation, with no adverse reaction. In a subsequent pediatric tibial nonossifying fibromas case, Tiedeman *et al.* (1991) also reported successful healing after injection of demineralized bone powder with autologous bone marrow.

Grafting bone marrow was also proven effective in medically compromised patients, for example, cancer patients, with delayed union or nonunions. Healey *et al.* (1991) reported bone marrow injections in eight patients with primary sarcomas, and bone formation was observed in seven patients after marrow injection, while complete healing was observed in five patients. Healey *et al.*

concluded that these encouraging results warranted further clinical studies and that their findings suggested a useful technique for the treatment of delayed unions and nonunions in difficult clinical circumstances.

In clinical spinal fusion applications, bone marrow combined with either demineralized bone matrix (DBM) or osteoconductive substrates also resulted in improved bone fusion rates. Results similar to autograft were observed in a retrospective posterior spinal fusion study examining 88 consecutive patients and comparing (1) autologous iliac crest bone graft, (2) freeze-dried corticocancellous bone without marrow, and (3) demineralized bone matrix plus autologous bone marrow. Success rates of 88% and 89% were observed in the autologous iliac crest bone graft and the demineralized bone matrix plus autologous bone marrow groups, respectively. The highest failure rate (28%) was obtained in the freeze-dried corticocancellous bone without marrow group. The authors concluded that augmentation of demineralized bone with bone marrow resulted in fusion rates similar to those of iliac crest bone graft (Price *et al.*, 2003). Similar findings have been reported with the use of synthetic grafting materials. Bone marrow aspirate combined with a mineralized collagen matrix (HEALOS®) produced similar fusion rates to those observed with autograft in a posterior spine fusion study (Kitchel, 2006).

While bone marrow was consistently reported clinically and preclinically to be as effective as autograft for bone repair, indications in animal models, as described earlier, suggested a relationship between the efficacy of marrow and its inherent cellularity (Kraiwattanapong *et al.*, 2005; Minamide *et al.*, 2005; Tay *et al.*, 1998). Clinically, bone marrow cellularity, as a function of age and gender, was evaluated by multiple groups; consolidated findings from these studies seemed to indicate that cellularity decreased rapidly in early years and after puberty. A slower but continued decrease in cellularity was observed subsequently during adult life; this effect was also found to be greater in women than in men (Muschler *et al.*, 2001). Other factors, such as air pollution particulates and nicotine, were found to affect bone marrow cellularity and bone marrow cell responsiveness (Liu *et al.*, 2001). Thus, in order to maintain the efficacy of bone marrow to regenerate bone despite decreasing cell numbers and reduced cell sensitivity, significant effort was geared toward creating methods to concentrate cells at a given repair site.

#### *Use of Concentrated-Stem-Cell Therapies*

##### *Point-of-Care Concentration Techniques — Use of Autogenic Cells*

Centrifugation was the first method utilized to concentrate osteogenic cells, initially based on protocols described by Friedenstein *et al.* in 1968. In 1989, Connolly *et al.* established a protocol to recover close to 100% of all nucleated

cells within a bone marrow aspirate, centrifuging marrow samples at 400 times gravity for 10 minutes. Connolly was among the first to suggest that concentrating bone marrow-derived nucleated cells on bone grafts would increase the bone-forming efficacy of the grafts. These investigations demonstrated that using a four fold cell concentrate of rabbit bone marrow significantly improved the bone-forming rate in a rabbit intraperitoneal chamber model.

The concept of concentrating cells became particularly attractive in challenging clinical cases, as, for example, in nonunions. Connolly utilized his centrifugation methods in the clinic and was able to achieve 100% healing in 18 cases of nonunion (Connolly, 1998). More recently, Hernigou *et al.* (2005) used the same centrifugation methods to inject concentrated bone marrow cells in tibial nonunions of 60 patients. In this study, a 4.2-fold cell concentration ratio was typically achieved (from  $612 \pm 134$  progenitors/cm<sup>3</sup> before concentration to an average of  $2579 \pm 1121$  progenitors/cm<sup>3</sup> after concentration). Union was obtained in 88% of cases (53 patients), and the bone marrow that had been injected into the nonunions of those patients contained an average of  $54,962 \pm 17,431$  progenitors. In contrast, the total number of osteoprogenitors injected in the seven patients who did not heal was significantly lower, at  $19,324 \pm 6843$  progenitors ( $p < 0.01$ ), than that of patients who healed. As seen in rabbits, the success of a bone graft in healing challenging defects was correlated directly with the number of cells implanted in that site. This study represented the first clinical attempt to quantify the required cell numbers for successful union.

To facilitate the cell concentration procedure in the operating room, Muschler *et al.* (2003) developed a point-of-care, disposable, cell-enrichment device. This method relied on the physical principles of an affinity column to populate a custom-designed graft matrix with a high proportion of osteoprogenitor cells found in bone marrow. The custom-design graft matrix for the cell-enrichment technology was engineered to be highly porous and to possess a high surface area for cell attachment. When marrow passed through this matrix at an optimized, controlled flow, nucleated cells attached while hematopoietic cells passed through. The result was a graft material that contained an increased concentration of nucleated and, more specifically, osteoprogenitor cells. Muschler *et al.* (2003) first tested the selective cell retention technology in a posterolateral fusion model in dogs. An established posterior spinal fusion model was used to compare (1) cell-enriched cancellous bone alone, (2) cancellous bone plus a bone marrow clot, and (3) cell-enriched cancellous bone plus a bone marrow clot. The hypothesis in this study was twofold: On one hand, cell enrichment would increase graft osteogenicity, and, in addition, adding a bone marrow clot to the graft would even further enhance its efficacy. Results from union score, quantitative computed tomography, and mechanical testing all demonstrated that the bone matrix plus enriched bone marrow clot was superior to all other groups. These data

**FIG. 56.2.** Representative x-ray radiographs 16 weeks postoperatively of canine critical-sized femoral defects implanted with (a) autograft and (b) cell-enriched demineralized bone matrix with cancellous chips clotted with platelet gels.

also confirm that cell enrichment significantly improved graft performance.

In a subsequent study, the actual cell concentrate was compared directly to whole bone marrow. Groups included (1) matrix alone (demineralized cortical bone powder), (2) matrix plus marrow, and (3) matrix with enriched marrow cells. Enriched matrix grafts delivered a mean of 2.3 times more cells and approximately 5.6 times more progenitors than matrix mixed with bone marrow. Again, union scores and fusion volumes both confirmed that selective cell retention improved healing outcomes (Muschler *et al.*, 2005).

Using the same selective cell retention methodology, Brodke *et al.* (2006) used a canine critical-sized segmental defect to evaluate the healing efficacy of cell-enriched grafts versus autograft. Canine demineralized bone matrix (cDBM) and cancellous chips were enriched in osteoprogenitors and placed in 21-mm-long osteoperiosteal femoral defects; animals were sacrificed 16 weeks postoperatively, and the femurs were removed and analyzed. The results showed equivalency between both the cell-enriched grafts and autograft. Both resulted in 100% bridging bone across the length of the defects (Figs. 56.2 and 56.3 illustrate fusion via radiography and CT). Histology sections further demonstrated bone formation across the defects in all autograft and cell-enriched cases (Fig. 56.4).

**FIG. 56.3.** Representative  $\mu$ CT scan of canine critical-sized femoral defects 16 weeks postoperatively implanted with (a) autograft and (b) cell-enriched demineralized bone matrix with cancellous chips.

Finally, a sheep model was also used to evaluate the healing potential of cell-enriched grafts using autologous bone marrow. In this model, the bone-grafting efficacy of tricalcium phosphate (CaP) grafts in three different configurations was evaluated: (1) CaP alone, (2) CaP saturated with whole bone marrow, and (3) CaP enriched with osteoprogenitor cells. (Graft placement in the gutter is shown in Fig. 56.5.) In this model, CaP enriched with osteoprogenitor cells reached 33% fusion, while autograft fused at only 25%. CaP alone did not result in any fusions, and CaP saturated with whole bone marrow reached only 8% fusion (three-dimensional CT reconstructions of fusions shown in Fig. 56.6) (M. C. Gupta *et al.*, in press). These results indicate once more that osteoprogenitor enrichment increased bone graft osteogenicity.

Human clinical evaluations of the cell-enriched grafts followed preclinical studies. A pilot clinical trial conducted at the Cleveland Clinic reviewed spinal fusion outcomes of 21 patients who received demineralized bone matrix enriched using Muschler's technique. Twenty out of 21 patients showed radiographic evidence of fusion at 12 months (Lieberman, 2004). This study was followed by a prospective, multicenter study. Fifty-one patients across five centers were included in the study. All underwent one- or two-level posterolateral fusions. Grafts were prepared using iliac crest bone marrow aspirate. Selective cell retention of the marrow was prepared on demineralized bone matrix. After 12 months, VAS scores were decreased favorably by an

average of 55% for back pain, 58.5% for right leg pain and 65.7% for left leg pain. Fusion rates were 84.2% (Wang *et al.*, 2005).

While fusion results using cell concentration techniques matched those obtained using autograft, a small percentage of patients, as seen with autograft, still did not show radiographic evidence of solid bone formation. It was hypothesized that cell numbers in these few patients was so drastically compromised that neither autograft — the gold standard — nor physiological cell-enrichment techniques could regenerate their bone. At the same time, recent evidence indicates that adult stem cells may not express immunologically relevant cell surface markers and, thus, could be harvested from an individual, grown in culture, and potentially implanted in another individual without being then rejected. A new approach was therefore envisioned for these high-risk patients: the use of allogeneic, culture-expanded

cells, stored in cell banks and ready for use at any time, such that concentration levels would now reach several hundred times native levels.

#### *Culture-Expanded Approaches — Use of Allogeneic Cells*

Key culture-expansion methodologies for bone marrow-derived mesenchymal stem cells were published starting in the late 1980s. Maniopoulos *et al.* (1988) first described a process to isolate osteoprogenitor cells from rat bone marrow. This technique involved explanting the entire femur of the rats and flushing the bone marrow in an osteogenic cell media. After 7–14 days, alkaline-phosphatase-positive colonies would become visible, indicating potential differentiation of osteogenic cells.

Cell-isolation methodologies were then developed to culture human bone marrow-derived cells, and Jaiswal *et al.* (1997) established a reproducible and standardized system for the *in vitro* osteogenic differentiation of human marrow-derived MSCs. Muschler *et al.* (1997) utilized similar cell-isolation techniques to quantify osteogenic precursors in bone marrow aspirates of patients.

As scientists deepened their understanding of osteoblastic cell growth and proliferation conditions, it was hypothesized that allogeneic MSCs might be applicable to bone repair and regeneration if one could successfully mute immunoreactive groups. Surprisingly, this turned out to be unnecessary, for *in vivo* evaluations of allogeneic MSC implantation consistently demonstrated a lack of immune response and rejection. In one instance, analysis of circulating antibody levels against MSCs nine weeks postimplantation in a canine cranial site supported the hypothesis that neither autologous nor allogeneic MSCs induced a systemic response by the host (Arinze *et al.*, 2003). The authors concluded that autologous and allogeneic MSCs had the capacity to regenerate bone within craniofacial defects (De Kok *et al.*, 2003). More recently, undifferentiated human MSCs were shown not to express immunologically relevant cell surface markers. They also seemed to inhibit the proliferation of allogeneic T-cells *in vitro*. Thus, MSCs could be described as immunoprivileged or immunomodulating cells (Niemeyer *et al.*, 2004). These findings confirmed that allogeneic stem cells could indeed become a possible therapeutic tool. As such, they are currently being developed for bone and soft tissue repair.

While no additional preclinical or clinical studies were conducted on the use of allogeneic cells, these cells became available in 2006 through a special regulation that allows human tissue to be commercialized in the United States with very limited regulatory scrutiny. Commercially-available cells are, however, not culture expanded but used at concentrations similar to those found in human bone.

While allogeneic culture-expanded stem cells could potentially be of value for high-risk patients, currently available preclinical evidence failed to demonstrate superiority of this technique over point-of-care cell-concentration

methods. To address this shortfall, it was hypothesized that the undefined marrow stromal environment, which is maintained when using point-of-care concentration techniques but is washed away when using culture-expanded cells, may affect bone formation in ways that are not yet clearly understood. This fact was based on two publications (Brodke *et al.*, 2006; Muschler *et al.*, 2003) that both highlighted the importance of bone marrow stroma or bone marrow clots for bone regeneration. Clearly, more research is needed to address these issues and other unknown parameters in bone regeneration.

### Ongoing Research

While most research from the 1960s to the late 1990s focused on understanding osteoprogenitor cells from the bone marrow, research groups also investigated other tissues that may provide clues or cellular responses related to bone formation. Was there another repository of stem cells that may be easily accessible and may provide cells that, for unknown reasons, would be more responsive than those found in the marrow? One key focus thus turned to another tissue, widely available among Americans and easily accessible: fat. Fat is the most convenient tissue other than bone marrow for harvesting MSCs, for it is easily biopsied, cultured, expanded, and transduced.

### New Autologous Sources for Stem Cells

Not surprisingly, cells derived from connective tissues such as muscle and fat were shown to “behave” similarly to bone marrow–derived MSCs: These cells, when cultured in the right conditions, would differentiate into bone, as seen with bone marrow–derived cells (Betz *et al.*, 2005). Interestingly, but again not surprisingly, these cells were shown to differentiate in many different connective tissues, i.e., bone, fat, cartilage, and muscle tissues, with growth factors specific to each culture condition (Zuk *et al.*, 2002). Surprisingly, however, cells derived from adipose tissue were shown to contain proliferative properties that did not decline with age. In addition, this tissue was described as a richer and more effective source of osteoprogenitor cells than bone marrow, one that could easily be modified to express BMP-2 (Dragoo, 2003).

While all these *in vitro* considerations were very intriguing, only a bone regeneration model *in vivo* would address whether or not these cells were suitable for bone regeneration. Cowan *et al.* (2004) used these cells to investigate the *in vivo* osteogenic capability of adipose-derived stromal (ADAS) cells to heal critical-sized mouse calvarial defects. These ADAS cells were harvested from the subcutaneous anterior abdominal wall, yielding ~800 mg of fat tissue, and were shown to be multipotent and available in large numbers. *In vitro*, they were observed to attach and proliferate rapidly. The authors also reported a yield of cells that, by itself, was much higher than that of typical bone marrow.

### Novel Approaches to Maximize Stem Cell Survival and Growth: Gene Therapy

Gene therapy was initially designed to allow transfer of genetic material into cells, which in turn secreted specific proteins that could affect cell migration, proliferation, and differentiation via an autocrine or paracrine effect. In this model, growth factors, unlike manufactured recombinant proteins, would be synthesized *in situ* as a result of gene transfer and would be presented to the surrounding tissue in a natural, cell-based manner. Local MSCs would then undergo osteogenic differentiation or secrete appropriate tissue and thus effectively form bone.

Gene therapy involves three fundamental elements: a sequence of DNA encoding a protein of interest, a vector that would facilitate the entry of genetic material into cells, and target cells for that gene segment. Two different types of therapeutic conditions could be envisioned for gene therapy: (1) conditions that require continuous, sustained delivery of specific proteins; and (2) conditions that require a one-time bone regeneration agent (e.g., trauma cases and spinal fusions). A commonly cited example of a clinical case requiring continuous, sustained delivery of proteins is osteogenesis imperfecta. In this case, a patient would be implanted with MSCs genetically modified with a retrovirus containing the gene for normal type I collagen. These cells would reestablish themselves in the bone marrow and thus provide mesenchymal progenitors with the appropriate collagen type I building capabilities.

For one-time bone repair applications (e.g., bone fractures, spinal fusions), gene therapy would generate short-term gene expression. Thus, nonviral vectors, which are typically easier to generate, more stable than viruses, and less immunogenic, were considered.

In addition to short- and long-term protein expression, two types of gene therapy approaches could be envisioned: a so-called *in vivo* approach as well as an *ex vivo* approach. *In vivo* gene therapy involved the direct transfer of genes into patients. In preclinical studies, this method was shown to be easy to perform but had relatively poor transduction efficiencies and could cause inflammatory responses. An *ex vivo* gene therapy involved transducing cells *in vitro* and then implanting those cells at a specific site. This approach presented several advantages, including direct delivery of the osteogenic gene to a desired site, targeted cell transduction for gene delivery, a supply of cells that participated directly in the osteoinductive process, and the potential for controlling the rate or extent of gene expression by using known vectors (Nussenbaum *et al.*, 2004). However, as discussed earlier, would the market support such a complex approach for clinical applications that have more than 90% success rate with available technologies?

Both *in vivo* and *ex vivo* gene therapies were tested in animal studies. In a preliminary study, Viggeswarapu *et al.* (2001) investigated *in vivo* gene therapy involving the LMP-1

gene in an adenovirus construct, which was used to transduce bone marrow–derived buffy-coat cells. These cells were implanted in a posterolateral fusion model in rabbits. All animals showed solid fusion at four weeks postsurgery. In a subsequent study, H. S. Kim *et al.* (2003) used a similar gene for *ex vivo* gene therapy in rabbits. In this study, the authors researched conditions to minimize immune responses and maximize fusion and found that minor protocol modifications, including doubling the viral dose or number of cells infected and increasing the infection time, could overcome immune complications. Bone formation and regeneration was also recently achieved in several different animal models, including rat femurs, mouse skulls, and porcine anterior spinal fusion.

While successful in these preclinical trials for one-time bone repair applications, it is worth mentioning that simple bone marrow aspirates also fused these challenging defects (Tay *et al.*, 1998). Thus, as of today, these techniques do not show superiority to the most accessible of all approaches presented in this chapter. Current thinking seems to indicate that the use of gene therapy for these applications may be unnecessary, since simpler and more economical approaches can effectively treat bone conditions such as fractures and fusions. Gene therapy, however, may be better suited for conditions that, like osteogenesis imperfecta, require continuous protein expression, since there is no currently available satisfactory treatment option to heal these pathologies.

As cell-based research progressed over the last decades, a parallel research arm focused on understanding growth factors to manipulate cells responsible for bone formation.

### III. GROWTH FACTOR-BASED THERAPIES

While bone growth factor research seemed to belong primarily to the pharmaceutical world, it has really been championed by the “bone device” industry. This was due primarily to the fact that these stimulants rely heavily on matrices that would contain them and allow them to be delivered in a specific fusion site. From a purely practical perspective, it also seemed reasonable that those companies involved in distributing orthopedic devices would also distribute the biological components required to heal bone.

#### Current Therapies

As with cellular approaches, the search for growth factors first focused on autologous factors that could easily be concentrated in the operating room. Growth factors were found to be readily stored in platelets, so platelet-concentration devices to be used at point-of-care sites became available on the market. A review of the scientific findings around platelet concentrates for bone repair is included below.

In addition to autologous factors, biotechnology provided the bone device industry with recombinant technologies that allowed mass production of naturally occurring bone morphogens. In 2003, the first such morphogen, recombinant human bone morphogenetic protein-2 (rhBMP2) entered the market for specific indications in spine fusion.

#### Autologous Sources: Platelet Concentrates

Marx *et al.* (1998) first evaluated the role of platelets in normal bone healing. His research led to the development of a whole new industry to develop and sell platelet concentrates for orthopedic and spinal applications.

Marx hypothesized that platelets, which were known to contribute to normal bone healing through the release of growth factors, could be concentrated and thus accelerate the healing cascade in a bone defect site. These platelet-derived growth factors had been shown to exhibit chemotactic activity as well as a mitogenic effect on osteoprogenitor cells. An important consideration in the use of concentrations of platelets [also called platelet gels or platelet-rich plasma (PRP)] was the fact that, by concentrating platelets instead of concentrating individual growth factors, an entire “cocktail” of factors would be concentrated and thus act in concert to increase bone fusion. Using clinical biopsy samples, Marx successfully demonstrated that these platelet gels could indeed accelerate the bone-healing process (Marx *et al.*, 1998; Marx, 2001).

As a result of Marx’s observations, multiple clinical studies were initiated to evaluate PRP in craniofacial (Aghaloo *et al.*, 2004), long-bone (Barrow and Pomeroy, 2005), and spine applications (Weiner and Walker, 2003). While most publications confirmed Marx’s observations, some manuscripts were controversial. Weiner *et al.*, in their posterolateral fusion study, even suggested an inhibitory effect due to PRP. This study prompted a series of investigations to understand exactly how the PRP used in these particular cases were prepared and whether anything in the preparation method could explain that unexpected outcome. Some critical clues were obtained from these observations: Premature platelet activation as well as plasma protein denaturation could result from inappropriate plasma preparation methods and could impact the efficacy of PRP (Kevy and Jacobson, 2004). Thus, critical care needed to be used in preparing these concentrates.

More recently, research focused on the use of platelet gels for diabetic patients. The fact that diabetics had lower base levels of growth factors — as low as one-third those of nondiabetics — had already been demonstrated in the early 2000s (Lu *et al.*, 2003). Interestingly, Gandhi *et al.* (2006) demonstrated that using PRP in a bony defect site of diabetic rats could play a significant role in promoting fracture healing.

While PRP was shown overall to promote bone healing and held promise for diabetic patients, it still maintained

the stigma of a technology that, while helpful, did not *consistently* demonstrate efficacy. Thus, the idea of a purified recombinant human factor provided to surgeons at a fixed concentration and thus, consistent efficacy, became increasingly attractive.

### Recombinant Human Proteins

A by-product of research performed on bone mineralization mechanisms, the discovery of bone morphogens within human bone matrix certainly accounted for one of the major milestones in bone research (Urist, 1965). Urist not only discovered BMPs, but also performed the first implantations of BMPs in humans in the late 1980s (Johnson *et al.*, 1988). It would take more than 20 years to get the first BMPs on the market: by 2006, rhBMP-2 had become available for interbody fusion and tibial repair, while rhBMP-7 was granted exemptions for humanitarian use in the treatment of recalcitrant tibial nonunions.

### rhBMP-2

Countless preclinical and clinical studies were performed with rhBMP-2, of which only a few are selected for review in this chapter. Using a rabbit posterolateral fusion model, Schimandle *et al.* (1995) reported 100% fusion in rabbits implanted with rhBMP-2 on a type 1 fibrillar collagen sponge. In this model, only 42% of sites implanted with autogenous bone graft from the iliac crest achieved fusion. Similarly, Sandhu *et al.* (1996) reported 100% posterolateral fusion in beagle dogs within 12 weeks after the implantation of rhBMP-2 on a collagen sponge. In this study, no fusions were observed with autogenous bone graft from the iliac crest.

As investigations evolved from smaller to larger animal species, doses required to achieve healing with rhBMP-2 needed to be increased. It was hypothesized that more evolved species contained fewer responsive cells and thus required higher concentrations of growth factor. Martin *et al.* (1999) showed that rhBMP-2 concentrations effective in lower animals (0.43 mg/mL) were not effective in posterolateral fusions in primates, and thus effective doses were increased to reach 1.5 mg/mL doses for human use.

On July 2, 2002, the U.S. Food and Drug Administration (FDA) cleared rhBMP-2 for distribution on a type I collagen sponge for use in combination with an LT cage for treatment of degenerative lumbar disc disease. This clearance followed a 279-patient clinical trial comparing rhBMP-2 with autograft. Two years following surgery, 94.5% of rhBMP-2-treated patients and 88.7% of autograft-treated patients achieved radiographic fusion without revision surgery (McKay and Sandhu, 2002).

rhBMP-2 on type I collagen sponges was also investigated in a posterolateral fusion model (Alexander and Branch, 2002). In this study, rhBMP-2 was found to be at

least as effective as autologous iliac bone for posterolateral reconstruction, in terms of promoting radiographic fusion. However, 58% of the rhBMP-2 patients demonstrated “greater than expected bone formation” dorsal to the cage, a finding seen in none of the controls. In 30% of the rhBMP-2 cases, this bone compromised the central canal, the neural foramen, or both. The study was halted and rhBMP-2 was deemed unsuitable for posterolateral construct. A following study was published in 2005, evaluating the use of rhBMP-2 in posterolateral applications with a compression-resistant matrix. In this study, 89% fusion was observed in patients implanted with a total dose of 40 mg rhBMP-2, a dose four times higher than that suggested for intervertebral fusion (Glassman *et al.*, 2005). This result was very similar to that observed in a comparable surgical setting using concentrated bone marrow aspirates (see earlier, Wang *et al.*, 2005), indicating that, whether using supraphysiological concentrations of growth factors or bone marrow cell concentrate, the percent healing rates for posterolateral fusions reached a plateau that these current technologies, when used separately, could still not overcome. rhBMP-7, also called rhOP-1, showed very comparable trends, as described later.

rhBMP-2 was also evaluated for efficacy in a long-bone-defect model. In a prospective, randomized, single-blind study, 450 patients with an open tibial fracture were randomized to receive either the standard of care (intramedullary nail fixation and routine soft-tissue management), the standard of care and an implant containing 6 mg of rhBMP-2, or the standard of care and an implant containing 12 mg of rhBMP-2. The primary outcome measure was the proportion of patients requiring secondary intervention because of delayed union or nonunion within 12 months postoperatively. The results indicated highest efficacy in the 12-mg group, and, in that group, superiority to the standard of care was achieved in reducing the frequency of secondary interventions. These results prompted the FDA to grant rhBMP-2 market approval for tibial fractures.

### rhOP-1

rhOP-1, following closely behind rhBMP-2 in terms of development timeline, demonstrated similar osteogenicity in preclinical and clinical models. Cook *et al.* (1994) demonstrated lumbar facet fusions in a dog model using rhOP-1 with a collagen-based carrier. All animals implanted with the rhOP-1 achieved stable facet fusion by 12 weeks, while animals implanted with autogenous bone graft achieved fusion only 26 weeks postoperative. Cunningham *et al.* (2001) studied posterolateral fusion in the dog using rhOP-1 and found that after 12 weeks, 27% of the posterolateral sites implanted with autograft had fused, 83% of the posterolateral sites implanted with autograft and rhBMP-7 had fused, and 72% of the sites implanted with rhBMP-7 alone had fused.

Interestingly, Den Boer *et al.* (2003) investigated the healing potential of ceramic grafts containing either bone marrow or rhOP-1 in a 3-cm segmental bone defect in sheep tibia. Five treatment groups were included: no implant, autograft, hydroxyapatite alone, hydroxyapatite loaded with rhOP-1, and hydroxyapatite loaded with autologous bone marrow. At 12 weeks, torsional strength and stiffness of the healing tibiae were about two to three times higher for autograft and hydroxyapatite plus rhOP-1 or bone marrow, compared to hydroxyapatite alone and empty defects. The mean values of both combination groups were comparable to those of autograft. Healing of bone defects, treated with porous hydroxyapatite, was enhanced by the addition of rhOP-1 or autologous bone marrow. The results of these composite biosynthetic grafts were equivalent to those of autograft.

So, while preclinical studies demonstrated the efficacy of rhOP-1 for bone repair, no evidence indicated an increased efficacy of the recombinant protein vs. native levels of bone marrow in animal models.

rhOP-1 was further investigated *in vivo*. Patel *et al.* (2001) presented the results of a safety and efficacy study using rhOP-1 in combination with autograft for posterolateral fusion. In this study, 16 patients with degenerative lumbar spondylolisthesis and stenosis were randomized to instrumented posterior spinal fusion and decompression with either autograft bone alone or a combination of autograft bone and rhBMP-7 with the collagen and CMC delivery vehicle. No instrumentation was used in this study. Six months following surgery, 9 of 12 (75%) patients in the autograft/rhBMP-7 cohort were graded fused, whereas 2 of 4 (50%) patients in the autograft alone group achieved fusion. While these results seem far less impressive than those obtained with rhBMP-2, it is important to remember that the indication that was used is significantly more challenging and, thus, may require a significantly stronger biological stimulant. Thus, a follow-up trial is currently ongoing for the evaluation and market approval of rhOP-1 in spinal applications.

For long-bone repair, rhOP-1 was compared to autogenous bone graft in a tibial nonunion study. This study successfully demonstrated that rhOP-1 was as efficacious as autograft, but it did not show any improved healing with rhOP-1 as compared to autograft (Friedlaender *et al.*, 2001). Accordingly, the FDA did not grant postmarketing approval (PMA) but instead approved a more limited humanitarian device exemption (HDE) for this application.

### Ongoing Research: New Growth Factors

Both rhBMP-2 and rhOP-1, as presented earlier, were shown to be equivalent to autograft in repairing bone. Therefore, the next generation of growth factors needed to present specific market edges or scientific improvements that would justify their use.

Key issues surrounding both rhBMP-2 and rhOP-1 were related to their long-term safety (Alexander and Branch, 2002;

Dawson, 2003). These long-term safety considerations really came down to these large quantities of growth factors needed in each case; for rhBMP-2, it was estimated that one dose for spinal surgery would equal about 100 times the native levels of BMP-2 in an entire skeleton. Such high doses could generate immune and/or tumorigenic responses. Therefore, the need for growth factors with similar osteoinductivity to both rhBMP-2 and rhOP-1 but with reduced potential for long-term risk emerged as a development opportunity.

In addition to safety concerns, both rhBMP-2 and rhOP-1 presented challenges in their delivery to the surgical site: An optimal carrier for growth factor still seemed to be missing in both cases. Thus, another development opportunity included improving the delivery of these factors through an optimized matrix material.

### Chrysalin

Chrysalin, a new growth factor currently in development by OrthoLogic Inc., has not been widely described in the literature. It is thus unclear whether Chrysalin would provide a clear scientific improvement over rhBMP-2 and rhOP-1. This growth factor may therefore only be developed to provide choices to surgeons.

Chrysalin was characterized as the 23-amino-acid fragment representing the natural amino acid sequence of the receptor-binding domain of human thrombin (prothrombin amino acids 508–530, TP508) (Glenn *et al.*, 1988). Used as a single injection, Chrysalin was shown to accelerate fracture repair in the mid-diaphysis of the rat tibiae by about 30–40%. Histological examination of the healing fracture indicated that this single injection of Chrysalin stimulated endochondral ossification. Callus formation was increased, resulting in increased resistance to torsional stress. Recent studies also showed that Chrysalin promoted cartilage formation in rabbit osteochondral defects (Grande *et al.*, 2002). Chrysalin's mechanism of action on endochondral ossification was studied by Schwartz *et al.* (2005) using an *in vitro* model of growth-plate cartilage regulation. Results indicated that Chrysalin promoted the cartilage extracellular matrix synthesis and, to some extent, chondroblastic proliferation, but did not significantly affect endochondral differentiation.

Because preclinical results seemed promising, Chrysalin entered a Phase III clinical trial to assess its effectiveness to accelerate healing of unstable, displaced distal radius fractures. Unfortunately, in early 2006, OrthoLogic Inc. reported that treatment with 10 µg of Chrysalin did not demonstrate a statistically significant benefit as compared to placebo in the primary efficacy endpoint of “time to removal of immobilization.”

With competitors such as rhBMP-2, OP-1, and recombinant human growth and differentiation factor 5 (rhGDF-5), it thus becomes unclear how Chrysalin would compete, yet alone gain marketing approval. A strategic repositioning

**FIG. 56.7.** Three-dimensional rendering of the recombinant human growth and differentiation factor-5 (rhGDF-5) structure. Circular dichroism of rhGDF-5 further confirmed presence of 2.4%  $\alpha$ -turns, 41%  $\beta$ -sheets, 8%  $\beta$ -turns, and 48% random structures.

of Chrysalin's value proposition in terms of health/cost benefits seemed necessary to bring this molecule to market. While the clinical trial addressed only the effect of Chrysalin on bone regeneration, it is possible that this molecule may be found effective with other clinical endpoints or for the repair of other connective tissues.

#### Recombinant Human Growth and Differentiation Factor-5

Recombinant human growth and differentiation factor-5 (rhGDF-5) was described as a subgroup-defining BMP family member with structural similarity to BMP-2 and BMP-7 (Fig. 56.7). Following its initial discovery in 1992, GDF-5 was further rediscovered in various tissues and by several unrelated research groups, all of which named the molecule differently. As a result, GDF-5 was called MP52, BMP-14, LAP-4, CDMP-1, and, more recently, radotermin (Triantafilou *et al.*, 2001; Hotten *et al.*, 1994). rhGDF-5's market "edges" over rhBMP-2 and rhOP-1 were twofold: (1) An optimized matrix (HEALOS®), on which rhGDF-5 is lyophilized, would improve the delivery of the growth factor in the surgical site, and (2) efficacy at lower doses would alleviate some of the long-term safety concerns.

HEALOS/rhGDF-5 was tested in a series of animal models, ranging from rats, rabbits, and sheep to nonhuman primates, and in long bones, flat bones, and spinal applications. Three key preclinical studies were most recently published in rabbits (Magit *et al.*, 2005) and sheep (D. H. Kim *et al.*, 2004; Jahng *et al.*, 2004).

Magit *et al.*, using the rabbit posterolateral fusion model, performed a randomized study using three different doses of HEALOS/rhGDF-5 bone graft (0.5 mg/cc, 1.0 mg/cc, and

**FIG. 56.8.** Representative radiograph of a sheep L4–L5 spine segment fused with HEALOS/rhGDF-5 six months postoperatively. HEALOS/rhGDF-5 was implanted on one side, while autograft was used on the other side. Surgeries were performed endoscopically.

1.5 mg/cc), as well as autograft and carrier-only controls. A total of 13 animals were included per arm (for a total of 65 rabbits) to ensure statistical relevance. The animals were maintained for eight weeks and then analyzed by manual palpation and histology. All animals implanted with HEALOS/rhGDF-5 fused at the eight-week endpoint. Less than 40% fusion was observed in the autograft arm, and no fusion was seen in the carrier-only controls. Histologically, the 0.5-mg/cc and 1.0-mg/cc doses resulted in the greatest bone volume formation.

HEALOS/rhGDF-5 was then evaluated in a variety of ovine spine fusion models. The first posterolateral fusion

study in sheep was performed by D. H. Kim *et al.* (2004). This study compared HEALOS/rhGDF-5 to autograft in an instrumented lumbar fusion model. Eleven skeletally mature, female sheep underwent intertransverse process spine fusion at two noncontiguous fusion segments, L2–L3 and L5–L6. Each animal was treated with autograft at one level and 0.5 mg/cc HEALOS/rhGDF-5 bone graft at the other level. At 6 and 12 months, fusion was assessed by manual palpation, radiography, and histology. Manual palpation indicated fusion at all treated levels, at both time points, a result that was further confirmed by radiographic analyses and histology. Histomorphometry was also performed on all samples and showed similar *de novo* bone volumes among all study groups. This study demonstrated that HEALOS/rhGDF-5 induced bone formation similar to autograft in a posterolateral, large-animal fusion model (Fig. 56.8).

In a second posterolateral fusion study in sheep, Jahng *et al.* (2004) investigated the use of HEALOS/rhGDF-5 for endoscopic surgery. The efficacy of 0.5 mg/cc HEALOS/rhGDF-5 was thus compared to autograft in an instrumented L4–L5 fusion model performed using an endoscopic approach. Twelve mature sheep were implanted with autogenous iliac crest bone on one side of the vertebral bodies and 0.5 mg/cc HEALOS/rhGDF-5 on the other side. Groups of four sheep each were euthanized at two, four, and six months postoperatively for manual palpation, radiography, and histological evaluation. No complications or ectopic bone formation were observed, confirming previous observations that rhGDF-5 does not induce bone in heterotopic sites. At two months, radiographic evaluation of the fusion sites showed the greatest bone growth in sites implanted

with HEALOS/rhGDF-5. At four and six months, solid posterolateral fusion was observed in both the autograft and the HEALOS/rhGDF-5 sites. These results reinforced previously recorded fusion rates and also highlighted the safety of HEALOS/rhGDF-5, since no ectopic bone formation was observed, a result that was particularly important in view of rhBMP-2's ectopic bone formation history in its aborted clinical trial. rhGDF-5 is currently undergoing clinical trials in the United States for use in the spine.

## IV. CONCLUSION AND FUTURE TRENDS

Significant progress has been achieved over the last several decades in bone-tissue regeneration. Specifically, in-depth understanding of bone marrow cells was critical to optimize the use of bone marrow in bone defects and develop methods of concentrating these osteogenic components to further enhance the healing potential of novel devices. In parallel, growth factors also significantly changed the therapeutic landscape and may continue to do so going forward.

As our understanding of the complex phenomenon of bone formation increases, there will be an increasing number of potent grafts and cell therapies available to help in bone-related surgical procedures. Short- and medium-term research may include new osteopromotive and osteoinductive growth factors for bone repair and bone fusion, as well as improved delivery systems for existing growth factors. In the long term, focus may shift to injectable formulations that could form bone *in situ* and would altogether alleviate the need for invasive surgeries.

### I. INTRODUCTION

Bone and cartilage reconstruction is an important area of tissue-engineering research. Tissue engineering offers a better approach than conventional surgery for bone and cartilage repair by reducing donor site morbidity. To achieve this goal, animal study of repairing clinically relevant tissue defects, especially in large animals, has become a crucial step.

Bone and cartilage tissue repair is an important task for plastic and orthopedic surgeons. One of the disadvantages of the traditional surgical repair procedure is the need to harvest autologous tissues from a donor site of the human body for the repair of a defect on another site, thus leaving a secondary tissue defect. Tissue engineering offers an approach to tissue repair and regeneration without the necessity of donor site morbidity. For practical applications, a series of experiments should be performed to prove the concept and the practical feasibility. In the initial phase, immunodeficient-animal models are usually used to screen all potential components of the proposed construct, such as matrix, cells, and signaling substances. In the second phase, an appropriate tissue-defect model in small animals is used to prove the principle of engineered tissue repair. In the preclinical phase, clinically relevant models are established

in large animals to study further the tissue formation process and the outcomes of engineered tissue repair in order to safely translate animal studies into human clinical trials. Regarding bone and cartilage engineering, a large number of studies have been performed in the initial and the second phases, according to the published literature. Based on these and our own results of early-phase studies, we have focused on tissue engineering and repair in large-animal models in the past few years and have further conducted clinical trials of bone repair in patients on a small scale. This chapter introduces our experience in bone and cartilage reconstruction in large-animal models and our experience in clinical trials of engineered bone repair of patients' craniofacial defects.

### II. BONE RECONSTRUCTION

As early as 1993, Vacanti *et al.* applied tissue-engineering techniques to the construction of bone grafts in the subcutaneous tissue of nude mice using periosteum-derived osteoblasts and degradable polymer scaffold, which clearly proved the concept that the tissue-engineering approach can regenerate bone tissue *in vivo* (Vacanti *et al.*, 1993; Vacanti and Upton, 1994). Later, more papers reported

success in repairing clinically relevant bone defects using the tissue-engineering approach.

Calvarial bone defect is a commonly used model to test the feasibility of bone engineering and repair in different animal studies and to define the role that seed cells or scaffold material plays in the bone repair process. Although relatively small, the mouse model is still being used for bone-engineering studies. Kaplan's group recently used silk as a scaffold material for bone engineering (Meinel *et al.*, 2005). In their study, human mesenchymal stem cells (hMSC) were first isolated and seeded on a porous silk fibroin scaffold, *in vitro* engineered for five weeks in a bioreactor, and then transplanted to repair the calvarial bone defects created in nude mice with a diameter of 4 mm. Their results showed that hMSC could undergo osteogenic differentiation on this novel scaffold and that *in vitro* engineered bone could achieve better reparative results than the cell-scaffold complex without *in vitro* engineering. In another study, Cowan *et al.* (2004) used adult male FBV mice to study engineered bone repair of a critical-sized calvarial defect using osteogenically induced adipose-derived stromal cells and PLGA scaffold. They created a defect in parietal bone with a diameter as large as 5 mm and then repaired the defect with PLGA seeded with adipose-derived stromal cells or osteoblasts. The results showed that apatite-coated PLGA seeded with either type of cells could completely heal the bone defects and thus demonstrated that adipose-derived stromal cells could serve as a cell source for bone regeneration as well as bone marrow stromal cells.

Compared to the mouse model, rabbit calvarial repair seems to be used more often. As early as 1999, Breitbart *et al.* used this model to determine the effect of BMP-7 gene on engineered bone formation. They transduced rabbit periosteal cells with retrovirus containing a human BMP-7 gene and then seeded them on polyglycolic acid scaffold for bone repair. After 12 weeks, better bone formation was observed both histologically and radiographically in the transduced cell group than in the nontransduced group. In a similar study, Chang *et al.* (2004) also demonstrated that BMP-2-gene-transfected bone marrow stem cells could repair the calvarial bone defect better than nontransfected stem cells when applied with biomaterial to the bone defect site. In several other studies, the rabbit calvarial model was used to test scaffold materials for bone formation. With this model, bioglass was proved not to be a proper scaffold material for repairing large-sized bone defects (Moreira-Gonzalez *et al.*, 2005). Dutta Roy *et al.*'s (2003) study showed that porous HA scaffolds with engineered macroscopic channels had a significantly higher percentage of new bone formation when compared with the scaffolds without channels in a rabbit calvarial defect model, which indicates that scaffold geometry can enhance the ability of a ceramic material to accelerate the healing of bone defects.

The bone-engineering studies in mouse and rabbit calvarial models provide convincing data that critical-sized

defects of flat bone in small animals can be completely healed with a tissue-engineering approach. However, these results may not necessarily represent the bone formation and repairing process in human beings, because low-level mammals usually have a stronger ability than human beings for tissue regeneration. In contrast, large mammals, such as the sheep, dog, and pig, may reflect better than small animals the actual bone formation process in human beings, which will provide a guide to clinical application. Therefore, in the past few years our center has focused on engineered bone formation studies in large mammals. For example, in a study of sheep cranial bone defect repair (Shang *et al.*, 2001), bone marrow stromal cells (BMSCs) were isolated, expanded, and osteogenically induced with dexamethasone,  $\beta$ -glycerophosphate, and vitamin D<sub>3</sub>. The induced cells were then mixed with calcium alginate to form a cell-scaffold construct for *in vivo* implantation. In created bilateral cranial defects (20 mm in diameter), the experimental side was repaired with a bone graft comprising *in vitro*-induced autologous BMSCs and calcium alginate. Histology demonstrated new bone formation at six weeks postrepair, which became more mature by 18 weeks (Fig. 57.1). Three-dimensional computed tomography (3D CT) scanning confirmed that the bone defects were almost completely repaired by engineered bone at 18 weeks. In contrast, the control defect, which was transplanted with calcium alginate alone, remained unrepaired (Fig. 57.2). Furthermore, chemical analysis showed that the engineered bone tissues contained a high level of calcium (71.6% of normal bone tissue), suggesting that engineered bone can achieve good mineralization.

As a gel form scaffold, calcium alginate might be more suitable for engineering injectable bone than flat bone. In addition, tight contact between host bone and implanted bone construct might be important for better regeneration of engineered bone *in vivo*, meaning a relatively solid scaffold material should be preferred. Furthermore, a scaffold with natural tissue structure and components should be more suitable for clinical trials. Considering these, we performed a similar study in a canine model by using demineralized bone matrix (DBM) and BMSCs (manuscript in preparation). First, bilateral bone defects with a size of 2 cm  $\times$  2 cm were created. Then a BMSC-DBM construct that had been preincubated in osteogenic medium for seven days was implanted on the experimental side. Similarly treated scaffold construct without cell loading was implanted in a defect on the other side as a control. As shown in Fig. 57.3, bone formation was observed on the experimental side and remained stable when examined by x-ray and 3D CT scanning at 12 months postimplantation, and the defect was well repaired by the engineered bone. Histology also verified the bone formation on the experimental side but not on the control side. Of note, the engineered bone formed cancellous bone structure instead of lamellar structure of natural calvarial bone (Fig. 57.4). As expected, the control

side remained unhealed when evaluated by X-ray and 3D CT scanning examination at 12 months. Only fibrotic tissue was observed in its histology (Figs. 57.3 and 57.4). This work demonstrated that DBM could serve as a suitable scaffold material for bone engineering in large animals, and it might be an appropriate material for clinical trials. Recently, Mauney *et al.* (2005) also demonstrated *de novo* bone formation after *in vivo* implantation of DBM seeded with human BMSCs. In addition, they found that the level of mineralization of DBM also has an influence on the osteogenic differentiation of seeded BMSCs.

Of interest is that engineered flat bone did not form a typical lamellar structure, as natural flat bone has. Instead, a cancerous bone structure was observed in engineered cranial bone. This phenomenon is probably due to the

lack of proper mechanical loading during engineered bone formation *in vivo*. Unlike the bone-engineering process, during development and growth a natural calvarial bone may sustain a continuous and long-term pressure from growing brain tissue and eventually forms a lamellar structure.

Therefore, an *in vivo* model that allows for bone remodeling by mechanical loading is particularly important for generating a bone that has the structure and mechanical strength similar to those of natural bone counterpart. Different from flat bone, weight-bearing long bones usually sustain mechanical loading in their physiological activities during their lifetime. These kinds of bones, including femur, tibia, and metatarsus, might be fit for such a model for engineering weight-bearing bone. In 2000, Petite *et al.* succeeded

in engineering a metatarsus in a sheep model using coral and bone marrow stromal cells and showed the feasibility of generating a weight-bearing bone in large animals.

Femur is the largest weight-bearing bone in animals and human beings. In a recently published study (Zhu *et al.*, 2006), we tested the possibility of engineering femoral bone in a goat model by using BMSCs and coral scaffold. As other studies reported, BMSCs were expanded *in vitro* and osteogenically induced and then seeded onto a natural coral scaffold

and cultured *in vitro* for one week before implantation *in vivo*. To provide a mechanical loading for the remodeling of the engineered bone, a special internal fixation device was developed that contains an internal fixation rod, with a diameter a little smaller than that of marrow cavity, and two sets of interlocking nails for fixing the rod at each end. After engineered bone formation, the interlocking nails can be removed, leaving the rod in the marrow cavity and thus allowing for mechanical loading by body weight.

In the surgical procedure, 22 adult goats, 12–14 months of age and weighing from 16.5 to 23 kg (an average of 19.6 kg), were included in this study and randomly divided into experimental group (implanted with cell–scaffold construct,  $n = 10$ ), scaffold control group (implanted with scaffold alone,  $n = 10$ ), and blank control group (without implantation,  $n = 2$ ). After anesthesia, the aspect of the right femoral shaft was exposed and a 25-mm-long (20% of the femur's total length) osteoperiosteal segmental defect was created with proper fixation by using the device. The defects then were treated with either cell-loaded scaffold, or scaffold alone or were left untreated.

Animals were sacrificed at either four months or eight months, respectively, for gross observation and histological and biomechanical analyses. In order to enhance tissue remodeling, interlocking nails were removed at six months in animals that would be sacrificed at eight months, to give the newly formed bone a mechanical loading.

As shown in Fig. 57.5, radiography examination demonstrated new bone formation one month after implantation at the site where BMSCs were implanted with coral. At six months, bone union was achieved at the defect site by engineered bone tissue, and so the interlocking nails were

**FIG. 57.5.** Radiographs taken of treated goat's femur at different time frames. (a–c) Femur defects treated with coral alone. (d–f) Femur defects treated with coral loaded with culture-expanded and osteo-induced BMSCs. (a) Femur defect treated with coral alone at day 1 after implantation. The cylinder with a density less than that of cortex can be found. (b) Coral density mostly disappeared at one month after implantation. (c) At eight months after implantation, minimal bone formation at the bone cut ends without bridging defect. (d) Femur defect treated with coral loaded with culture-expanded and osteo-induced BMSCs at one month after implantation. The shape of the implant was maintained, with callus formation at the interface to the bone cut ends. (e) At six months after implantation, newly formed bone can afford weight bearing after removing the interlocking nails. (f) At eight months after implantation, the density of newly formed bone is equal to that of cortex. Reprinted by permission of *Tissue Engineering* from Zhu *et al.* (2006).

Newly cancellous bone formed, with red color. **(b)** Femur defect implanted with coral loaded with culture-expanded and osteo-induced BMSCs at eight months. White-colored, remodeled cortex formed. **(c)** Femur defect implanted with coral alone at eight months. Nonunion formed. **(a–c)** Left, experimental bone defects; right, normal bone serving as a positive control. Reprinted by permission of *Tissue Engineering* from Zhu *et al.* (2006).

**FIG. 57.7.** H&E staining of repaired bone tissues. **(a)** Femur defect treated with coral alone at four months after implantation. Residual coral particle remained, surrounded by fibrous tissue (arrow,  $\times 100$ ). **(b)** Femur defect treated with coral alone at eight months after implantation. Coral particle disappeared completely, and a certain level of bone formed at bone cut end (arrow,  $\times 100$ ). **(c)** Femur defect implanted with coral loaded with culture-expanded and osteo-induced BMSCs at four months. Coral completely disappeared and woven bone was formed. White regions indicated by arrows are newly formed medullary canal ( $\times 100$ ). **(d)** Femur defect implanted with coral loaded with culture expanded and osteo-induced BMSCs at eight months. Mature bone structure was formed and Haversian system became observable (arrow,  $\times 100$ ). Reprinted by permission of *Tissue Engineering* from Zhu *et al.* (2006).

removed. After two months of mechanical loading, the engineered femur was further remodeled to become a mature bone. As observed radiologically, cortex bone was formed at eight months postimplantation. Interestingly, marrow cavity formation inside the engineered bone was also observed at this time point. Grossly, the engineered bone also exhibited an appearance similar to that of natural femoral bone (Fig. 57.6). Histology demonstrated the formation of trabecular and woven bone at four months. At eight months, the engineered bone became obviously more mature. Although still being an irregular pattern, the formed Haversian system became observable, indicating that mechanical loading plays an important role in the remodeling of engineered

bone (Fig. 57.7). In contrast, implantation of scaffold alone without cell seeding could not generate a femoral bone tissue sufficiently to achieve a bone union both grossly and histologically (Figs. 57.5, 57.6, and 57.7).

In addition to structural restoration by engineered bone, functional recovery is an important requirement for engineered bone repair. In this study, a three-point bending test demonstrated that engineered femoral bones at eight months were much stronger than those of four months. In addition, no significant difference was found with respect to bending load strength and bend rigidity between the eight-month engineered bones and natural counterpart bones. However, the engineered bones were still inferior to natural

**FIG. 57.8.** Three-dimensional CT and histological evaluation of the clinical repair of a cranial defect with tissue-engineered bone. *Top left:* Before operation. *Top middle:* Three months postrepair. *Bottom left:* Twelve months postrepair. *Bottom middle:* Five years postrepair. *Top right:* Bone biopsy; *bottom right:* biopsy shows cancellous bone structure of engineered bone at 18 months postrepair (HE).

bones with regard to bend intention and bend displacement (Zhu *et al.*, 2006).

### III. CLINICAL APPLICATION OF ENGINEERED BONE

Vacanti *et al.* (2001) performed the first clinical trial of engineered bone in thumb reconstruction, using autologous osteogenic precursor cells isolated from periosteum and initially appeared to have succeeded. However, long-term follow-up was not reported. Recently, Warnke *et al.* (2004) reported successful clinical treatment of mandibular bone defect in a male patient with tissue-engineered bone. A titanium mesh cage with the mandibular shape of the patient was first filled with bone mineral blocks infiltrated with recombinant human BMP-7 and bone marrow mixture and then implanted into the patient's latissimus dorsi muscle for seven weeks to form a vascularized bone graft. The combined engineered bone graft was then transplanted functionally to repair the mandibular defect, and the bone remodeling and mineralization was also observed via scintigraphy examination.

Our center initiated a clinical trial of engineered bone around 2001, focused mainly on the repair of human cranio-maxillofacial bone defects using autologous BMSCs and demineralized bone matrix (Chai *et al.*, 2003). As a typical case, shown in Fig. 57.8, we started the clinical trial on a small-size cranial defect. Bone marrow was harvested from

the patient to isolate BMSCs. After *in vitro* expansion and osteogenic induction, cells were seeded on DBM scaffold and *in vitro* cultured for seven days and then implanted to repair the patient's defect. As illustrated by 3D CT scanning, bone formation was observed at three months postimplantation and maintained stable when followed up at 12 months and five years postoperation. During a secondary revision operation, a bone biopsy was taken at 18 months postimplantation, and the histology showed a typical structure of cancellous bone. Therefore, we proved that engineered bone could form and remain stable long term in the human being. Based on the success in small-size bone repair, we further challenged ourselves to repair a craniofacial bone defect of larger size and more complicated 3D structure. Figure 57.9 demonstrates another typical case. The patient had a craniofacial bone defect involving both frontal and orbital roof bones. To proceed with the repair, the patient's 3D CT scanning data were first obtained and then used to 3D-print a mold that was fit exactly into the defect site. According to the 3D shape of the mold, DBM materials were trimmed and assembled to form a 3D-shape scaffold. After cell seeding and *in vitro* culture for seven days, the cell-scaffold construct was implanted to repair the defect. The patient has been followed up for up to three years with 3D CT scanning, which demonstrated that engineered bone not only satisfactorily repaired the defect with complicated 3D structure, but also remained stable without absorption even after three years. Our clinical trial results indicate that tissue

**FIG. 57.9.** Three-dimensional CT evaluation of clinical repair of a complicated craniofacial bone defect with tissue-engineered bone. *Left:* Before operation. *Middle:* One year postrepair. *Right:* Three years postrepair.

**FIG. 57.10.** Macrograph of a right knee joint harvested from the experimental group 24 weeks postrepair. **(a)** Gross examination shows that the defects are completely repaired by the engineered cartilage (arrows), leading to a smooth joint surface indistinguishable from the surrounding normal cartilage. **(b)** A cross section demonstrates ideal interface healing with the adjacent normal cartilage (arrowheads). engineering will become a novel approach for bone regeneration and repair.

#### IV. CARTILAGE RECONSTRUCTION

As with bone tissue, the proof of concept of cartilage engineering was performed in the subcutaneous tissue of the nude mouse (Vacanti *et al.*, 1993). In 1997, Cao *et al.* reported that cartilage with a complicated 3D structure, such as the human ear shape, could be engineered using nude mouse as an animal model, which reveals the great potential for the clinical application of engineered cartilage (Cao *et al.*, 1997). With regard to clinically relevant models for cartilage engineering and repair, articular cartilage repair is the most commonly involved subject; others include tracheal cartilage and meniscus.

Repairing an articular-cartilage defect using tissue engineering was reported many years ago (Wakitani *et al.*, 1989; Chu *et al.*, 1995; Grande *et al.*, 1997; Richardson *et al.*, 1999). While some studies focused on repairing a cartilage defect in small-animal models using allogenic chondrocyte-engineered hyaline cartilage (Wakitani *et al.*, 1989), our center has tried to repair the osteochondral defect in large

mammals using autologous chondrocyte-engineered cartilage (Liu *et al.*, 2002). In a porcine model, autologous articular cartilage at a non-weight-bearing area was harvested from the knee joint on one side. On the other side, an 8-mm full-thickness articular-cartilage defect deep to the underlying cancellous bone was created at both weight-bearing areas of the medial and lateral femoral condyles. The cell-scaffold construct containing polyglycolic acid (PGA), polyethylene-polypropylene hydrogel, and chondrocytes was then transplanted to repair the defects in the experimental group. In the control group, the defects were either transplanted with scaffold material alone or left unrepaired.

Grossly, cartilage tissues were formed in the defects of the experimental group as early as four weeks after transplantation. Histological examination demonstrated the presence of hyaline cartilage tissue. At 24 weeks postrepair, gross examination revealed a complete repair of the defects by engineered cartilage, shown by a smooth articular surface indistinguishable from nearby normal cartilage. A cross section revealed ideal interface healing between the engineered cartilage and the adjacent normal cartilage (Fig. 57.10). Histological analysis of the tissue harvested from

repaired defects further revealed a typical structure of cartilage lacuna and ideal interface healing to adjacent normal cartilage as well as to underlying cancellous bone (Fig. 57.11). Moreover, the engineered cartilage exhibited an enhanced extracellular matrix production and improved biomechanical properties, indicating that engineered cartilage resembles the native articular cartilage not only in morphology and histology, but also in biochemical components and biomechanical properties as well. Unfortunately, the subchondral bone defect was also repaired by the engineered cartilage rather than by engineered bone (Fig. 57.10), suggesting that chondrocytes may not be an optimal cell source to achieve a physiological repair of both cartilage and subchondral bone defects for an articular osteochondral defect. Other cell sources for optimal repair need to be investigated. In recent years, a few clinical trials of matrix-induced autologous chondrocyte implantation have been conducted in the treatment of articular cartilage lesions (Bartlett *et al.*, 2005; Marcacci *et al.*, 2005). Positive outcomes have been achieved in short-term and long-term follow-up (up to five years). The encouraging clinical results obtained indicate that autologous chondrocyte implantation is a safe and effective therapeutic option for the treatment of articular-cartilage lesions.

Although chondrocytes are a useful seed cell source for cartilage engineering and are relatively safe for clinical treatment, immune rejection will still be the major obstacle to the use of allogenic chondrocytes (Malejczyk *et al.*, 1991; Moskalewski *et al.*, 2002), and the use of autologous chondrocytes will face the challenge of donor site morbidity and limited cell source due to their limited expansion capacity, cell aging, and dedifferentiation during *in vitro* expansion (Parsch *et al.*, 2002, 2004). In addition, our experience indicates that chondrocytes are not appropriate to bony repair of an osteochondral defect (Liu *et al.*, 2002). Therefore, chondrocyte-based therapy may not be optimal for clinical applications. In contrast, mesenchymal stem cell-based therapy may potentially avoid these disadvantages. Recent studies showed that BMSCs have become a reliable replacement for chondrocytes due to their capability for chondrogenic differentiation and rapid proliferation (Pittenger *et al.*, 1999; Gao and Caplan, 2003). There have been many reports in the past decade of *in vitro* chondrogenic induction of BMSCs, and the induced cells could express chondrocyte-specific molecules, such as type II collagen, aggrecan, and Sox 9 (Mastrogiacomo *et al.*, 2001; Winter *et al.*, 2003; Fukumoto *et al.*, 2003; Williams *et al.*, 2003; Evans *et al.*, 2004). Moreover, several reports have demonstrated that induced BMSCs actually formed cartilage tissue *in vivo* (Wakitani *et al.*, 1994; Im *et al.*, 2001; Fuchs *et al.*, 2003; Gao *et al.*, 2004; Wayne *et al.*, 2005).

The repair of articular cartilage with BMSCs has been reported for many years. However, most of these studies focused on small-animal models, such as rats (Oshima *et al.*,

**FIG. 57.11.** Histology of tissues harvested at cartilage defects 24 weeks postrepair. In the experimental group, histological examination demonstrates a typical structure of hyaline cartilage lacunae (a, b). In addition, engineered cartilage heals ideally at the interface with the surrounding normal cartilage (a) and the underlying cancellous bone (b). In contrast, the defect in the control group is repaired by fibrous tissue and fibrocartilage. A poor interface healing to the adjacent cartilage tissue is also observed (c). Abbreviations: N, normal cartilage; I, interface healing; R, repaired tissue; C, cancellous bone. (H&E staining; original magnification,  $\times 100$ .) Reprinted by permission of *Tissue Engineering* from Y. Liu *et al.* (2002).

**FIG. 57.12.** Gross and cross-sectional view of repaired defects at six months postrepair. Arrows indicate the repaired regions. The experimental defect exhibits a relatively regular surface (Exp, **a**) and the osteochondral defect is completely repaired with both engineered cartilage and bone when observed at the cross section (**c**). The repaired surface of control group 1 remains irregular (Ctrl 1, **a**), but the osteochondral defect is mostly repaired at the cross section (**d**). The defects in control group 2 (Ctrl 2, **b**, **e**) and control group 3 (Ctrl 3, **b**, **f**) remain largely unrepaired at both cartilage and bony layers. Reprinted by permission of *Tissue Engineering* from Zhou *et al.* (2007).

2004, 2005) and rabbits (Im *et al.*, 2001; Gao *et al.*, 2004). Due to the differences in species and defect size, the data obtained from small animals might be inappropriate to elucidate the repair mechanism in human beings. In addition, there is still controversy regarding the true cell source (endogenous vs. exogenous) for the engineered repair of osteochondral defects, although some related studies have been performed in small animals using labeled seed cells (Oshima *et al.*, 2004, 2005). This is particularly true in large-animal model studies, in which no direct evidence has yet been provided. Therefore, two issues remain worthy to explore in this area: (1) discovering whether the approach is feasible or not in large animals for engineered repair of an articular osteochondral defect using autologous BMSCs,

especially for a long-term study; and (2) providing more convincing evidence to demonstrate the true cell source of repaired cartilage and its subchondral bone. To address these concerns, we recently performed a study of repairing articular osteochondral defect with autologous BMSCs in a total of 18 pigs using the previously established porcine model (Zhou *et al.*, 2006). BMSCs were isolated from hybrid pigs' marrow and treated with dexamethasone (40 ng/mL) alone or chondrogenically induced with dexamethasone and transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1, 10 ng/mL). The cells were then seeded, respectively, onto polylactic acid (PLA)-coated PGA scaffolds to generate cell-scaffold constructs. Four osteochondral defects in each animal were created at non-weight-bearing areas of knee joints (two

**FIG. 57.13.** Histology of repaired tissue at six months postrepair. The repaired regions are indicated between black arrows. **(a)** Histologic view of repaired tissue in the experimental group by Toluidine blue staining, a representative of *complete repair*. The rectangular region indicates the interface area (a1,  $\times 10$ ), which lies between the normal and engineered tissues. In the amplified view (a2,  $\times 40$ ), a white arrow indicates the interface line between native (left) and engineered (right) tissues. Interestingly, a nearly normal tidemark structure is observed in the engineered tissue, as indicated by the gray arrow. **(b)** Histologic view of repaired tissue in control group 1 by Toluidine blue staining, a representative of *incomplete repair*, which shows a relatively poor tissue structure in cartilage repair area (b1,  $\times 10$ ). In an amplified view (b2,  $\times 40$ ), normal articular tissue structure (hyaline cartilage and cancellous bone) is observed at a normal region (left side of the interface, as indicated by the white arrow) with an obvious tidemark structure. At the repaired area (right side of the interface), however, the repaired tissue is composed mainly of fibrocartilage and cancellous bone. Additionally, no mature tidemark structure is observed at the repaired osteochondral junction area (gray arrow). **(c)** Histologic view of repaired tissue in control group 2 by HE staining and Toluidine blue staining, a representative of *no repair*. The defect area is filled by fibrotic tissue (c1, HE,  $\times 10$ ) and shows no metachromatic matrix staining (c2, Toluidine blue,  $\times 10$ ). defects/side). Chondrogenically induced BMSC-PGA/PLA constructs were implanted in the defects of the experimental group (Exp). In control groups, the defects were repaired with dexamethasone-treated BMSC-PGA/PLA (Ctrl 1) constructs or PGA/PLA construct alone (Ctrl 2) or left unrepaired (Ctrl 3). To trace the implanted BMSCs, cells were retrovirally labeled with green fluorescent protein (GFP) before implantation.

The results showed that cartilage tissue was formed in the experimental group defects as early as three months after transplantation, and an improved result was achieved after six months. Additionally, the experimental group achieved the best reparative results among all tested groups. Grossly, most of the defects in this group were repaired by newly formed cartilage-like tissue with relatively regular surfaces (Fig. 57.12a). Cross sections showed fine interface healing between repaired tissue and normal osteochondral tissues. The thickness of repaired cartilage approached a

level similar to that of adjacent normal cartilage. Interestingly, both cartilage and bony defects were satisfactorily repaired by engineered cartilage and bone, respectively (Fig. 57.12c). However, in control group 1, only some defects achieved satisfactory repair with relatively smooth articular surfaces and relatively normal osteochondral structures, but most defects showed irregular surfaces in the central area of the defects and poorly repaired subchondral bone (Fig. 57.12a, d). As expected, defects of control group 2 and control group 3 healed poorly, showing unrepaired defect and partial formation of osteochondral tissue only at the interface between the defect areas and the native tissue areas (Fig. 57.12b, e, f).

Histology also showed that the experimental group achieved the best results. Most defects exhibited the structures of mature hyaline cartilage and cancellous bone, with cellular density and cartilage thickness similar to those of normal tissues (Fig. 57.13a1). Importantly, a nearly normal

**FIG. 57.14.** GFP expression in the repaired cartilage and cancellous bone at seven months postrepair by laser confocal microscope ( $\times 200$ ). **(a)** GFP-labeled BMSCs are evenly distributed in repaired cartilage area and form typical lacuna structures (arrows). **(b)** GFP-labeled BMSCs also contribute to the bony repair of subchondral bone. *Top panels:* Images under regular light (a1, b1); *bottom panels:* images under fluorescence light (a2, b2). Reprinted by permission of *Tissue Engineering* from Zhou *et al.* (2007).

tidemark could be observed between repaired cartilage and cancellous bone. Strong metachromatic matrix production and satisfactory interface healing were also observed, despite the fact that a tiny difference between repaired tissue and native articular tissue remains observable (Fig. 57.13a2). The results were less satisfactory in control group 1 because only some of the defects were repaired by the mature hyaline cartilage and cancellous bone. Yet the tissue quality remained inferior to that of the experimental group. In addition, a larger part of the defects in control group 1 showed fibrocartilage repair and the lack of an obvious tide-mark at the osteochondral junction (Fig. 57.13b1, b2). In contrast to the experimental group and control group 1, the defects of control groups 2 and 3 showed mainly fibrotic repair, with poor interface healing and poor metachromatic matrix staining at the area with the most defects (Fig. 57.13c1, c2). All these results indicate that implanted cells play an important role in tissue regeneration and repair and that *in vitro* chondrogenic induction is beneficial for that *in vivo* cartilage regeneration.

To further determine the fate of implanted BMSCs and the cell source for osteochondral tissue formation, confocal microscopy was used to examine the tissue sample in which GFP-labeled BMSCs were implanted. As shown in Fig. 57.14,

GFP-labeled cells remained observable at both cartilage and subchondral bone layers, even at seven months postoperation. Importantly, these GFP-labeled BMSCs actually formed typical lacuna structures (Fig. 57.14a1), suggesting that the implanted BMSCs have differentiated into both chondrocytes and osteoblasts, respectively, in their respective *in vivo* environments and that implanted BMSCs are the vital cell source for the osteochondral tissue repair.

Biomechanical property analysis of the repaired cartilage showed that the compressive moduli increased with postrepair time. At three months, the moduli reached 43.82% and 30.37% of normal cartilage level, respectively, in the experimental group and control group 1, and they further increased to 80.27% and 62.69% at six months postrepair. In addition, the glycosaminoglycan content of the experimental group reached 93.25% of normal content, with no significant difference between the native cartilage group and the experimental groups ( $p > 0.05$ ). Thus, BMSC-mediated repair not only restores the osteochondral tissue structure, but also generates the tissues with mechanical property and biochemical components similar to those of natural osteochondral tissues.

The foregoing study demonstrated that BMSCs are a better cell source than chondrocytes to achieve tissue-

engineered repair of an articular osteochondral defect. In addition, it also proves that implanted BMSCs can differentiate into both chondrocytes and osteoblasts in their related *in vivo* niches. Encouragingly, there are already a few reports of clinical trials of repairing articular-cartilage defect using BMSC-engineered cartilage, although the therapeutic effect needs to be improved further (Wakitani *et al.*, 2002).

Besides articular-cartilage repair, we succeeded in the repair of meniscal defects in a porcine model (Liu *et al.*, 2003). The meniscus was first harvested from one side to isolate meniscal fibrochondrocytes. A full-thickness meniscal defect (1 cm long) was then created on the other side, and the two ends of the defect were bridged by an acellular intestinal submucosa membrane that wrapped around the ends. Inside the membrane tube, PGA fibers mixed with polyethylene–polypropylene hydrogel and fibrochondrocytes were transplanted. In the control group, biomaterial alone was used. Grossly, the engineered tissue resembled native meniscus in morphology, color, and texture at 25 weeks posttransplantation of the cell–scaffold construct. Histologically, the engineered meniscus displayed a structure typical of fibrocartilage tissue, similar to that of native meniscus (Fig. 57.15). As expected, no meniscus tissue was formed in the control group.

*In vitro* cartilage engineering is an important area to pursue. We have succeeded as well in engineering cartilage tissue in the culture dish by using chondrocytes and polyglycolic acid (PGA) unwoven fibers, such as tracheal tubular cartilage (Fig. 57.16, *left*). However, BMSCs might be a better cell source than chondrocytes for cartilage engineering, as already described. As shown in Fig. 57.16 (*right*), cartilage tissue could be generated using PGA unwoven fibers and chondrogenically induced BMSCs. A future direction will be to engineer cartilage tissue with a 3D structure, like the human ear shape, by using BMSCs so that engineered cartilage can be used in clinical application.

## V. CONCLUSION

Many studies, including ours, have demonstrated the feasibility of bone and cartilage reconstruction in small and large animals using tissue-engineering techniques. BMSCs have been shown to be a preferred cell source for tissue reconstruction. In addition, clinically relevant tissue defects could be repaired by engineered bone and cartilage in large mammals. Moreover, the success in clinical trials of repairing patients' craniofacial defects with engineered bone reveals the promising future of tissue engineering as a favored approach for bone and cartilage reconstruction.

## VI. ACKNOWLEDGEMENTS

The authors would like to thank Drs. Lei Cui, Yulai Weng, Ming Wang, Zhuo Wang, and Lian Zhu for their contributions in bone engineering and Dr. Gang Chai for clinical trials of engineered bone. We also appreciate the contribution to cartilage engineering from Drs. Guangdong Zhou, Yanchung Liu, Fuguo Chen, and Tianyi Liu. The research

projects are supported by the National “973” (2005CB522700) and “863” Project Foundation, the Shanghai Science and Technology Development Foundation, and the Key Laboratory Foundation of the Shanghai Education Committee.

### I. INTRODUCTION

The intervertebral disc (IVD) is the fibrocartilaginous part of a “three-joint complex” that governs motion, flexibility, and weight bearing in the spine (Fig. 58.1). As part of this complex, the disc undergoes a lifetime of “wear and tear” that contributes to multiple IVD disorders of enormous consequence for human disability and suffering. These IVD disorders are poorly understood musculoskeletal pathologies characterized by multiple anatomic features, including internal disc disruption, IVD tears, and herniated disc fragments (Andersson, 1996; Bodguk, 1988; Boos *et al.*, 2002). These anatomic features are believed to associate with nerve root compression or irritation, spinal canal narrowing (stenosis or spondylolisthesis), or loss of disc height, which contribute to symptoms of low-back pain, neurological deficits, and disability that affect between 4% and 33% of the U.S. population annually (Hurri and Karppinen, 2004; Praemer *et al.*, 1999; Woolf and Pfleger, 2003). Like most cartilaginous tissues, the IVD is an avascular and alymphatic structure that exhibits little to no capacity for repair following injury and experiences aging-related cell density losses that may further limit biologically mediated repair (Urban and

Roberts, 2003). The extreme mechanical demands on the IVD may also contribute to tissue failure and degeneration, due to the high magnitudes of pressure, compressive, tensile, and shear stresses, and strains that result from joint loading, muscle activation, and spinal flexibility. As a result, strategies to intervene in the progression of IVD disorders are met with significant biological and mechanical challenges that frustrate success.

Numerous surgical procedures have been developed to treat IVD disorders, focused largely on bony fusion across the disc space to restore stability and eliminate symptomatic motions and weight bearing. The majority of these procedures have relied on fixation of devices to inhibit motion during the bony fusion process. In cases where the pathology permits, removal of extruded IVD fragments may be performed in a procedure termed *discectomy*. Together these procedures comprise more than 300,000 inpatient hospitalizations annually in the United States alone (DeFrances and Podgornik, 2006). More recently, intervertebral disc replacements have been approved as an alternative therapy to bony fusion for disc-related pathologies (McAfee, 2004). The concept for these “motion-preservation devices”

**FIG. 58.1.** Schema of spinal motion segment illustrating location of intervertebral disc between superior and inferior vertebral bodies. (Left) MRI appearance of immature lumbar disc with characteristic intense nucleus pulposus region. (Right, top) Gross appearance of nondegenerate lumbar disc and (right, bottom) histological appearance of immature disc in a stained section. Modified schema reprinted with permission from Columbia-Presbyterian Neurosurgery at [www.cumc.columbia.edu/dept/nsg](http://www.cumc.columbia.edu/dept/nsg).

is that maintenance of load sharing across the IVD and a small range of motion are important to provide full range of spinal motion, to maintain IVD health, and to minimize IVD height loss, facet joint degeneration, stenosis, and related symptoms that may occur in progressive IVD pathology. These devices present all the risks associated with conventional joint replacements, such as subsidence, wear, and failure, and are indicated for only a small portion of symptomatic pathologies. There exists a very compelling need to develop alternative strategies not only to treat the consequences of IVD disorders, but also to detect and limit the progression of symptomatic IVD pathology.

Success with cellular therapies for articular-cartilage regeneration, gene therapy, and *in vitro* regeneration of cartilaginous tissue has raised hope for tissue-engineered treatments for IVD disorders. Tissue-engineered approaches to IVD regeneration have been focused on implantation of cell-supplemented or acellular biomaterials that may partially replace the IVD structure as well as on delivery of cells or bioactive factors designed to promote the natural repair process. In this chapter, a review of these tissue-engineering strategies is provided, along with evaluations of their adaptation and implementation for treatment of IVD disorders.

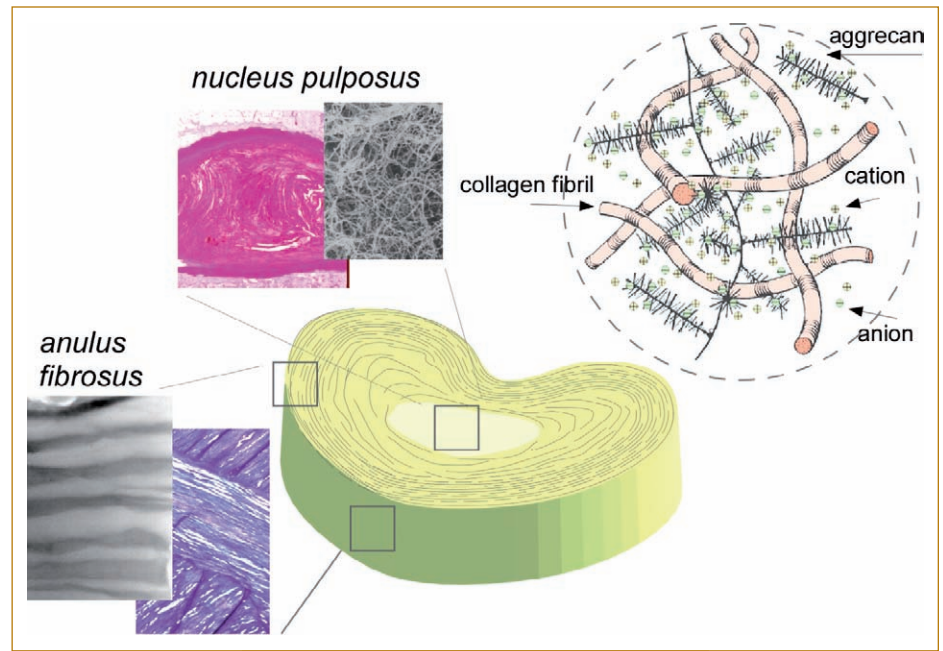

## II. IVD STRUCTURE AND FUNCTION

In all structures of the IVD, the extracellular matrix provides physical and biochemical cues that regulate cell-mediated repair or breakdown in mature or aging tissues (Oegema, 1990, 2002). The native matrix organization and interaction with the local IVD cell population will be important considerations in the design of any tissue-engineered regeneration strategy. The IVD is composed of a centrally situated and gelatinous tissue, the nucleus pulposus, which differs substantially from the more fibrocartilaginous anulus fibrosus, on the radial periphery (Fig. 58.2). On both superior and inferior faces is a cartilaginous endplate that provides an intimate mechanical and biophysical connection between the vascularized vertebral bone and the avascular IVD. Both

the anulus fibrosus, with a vascularized periphery, and the cartilaginous endplates are believed to be important routes of nutrient transport to all cells of the IVD (Nachemson *et al.*, 1970; Urban *et al.*, 1977). Given the very low cell density of the IVD, maintenance of both cellularity and a generous nutrient supply are often held to be critical to a successful biologically based regenerative strategy.

The immature nucleus pulposus is highly hydrated (>80% water), with extracellular matrix components that include randomly organized type II collagen fibers and multiple forms of negatively charged proteoglycans (Table 58.1, Roughley, 2004). A population of large and highly vacuolated cells is present in the nucleus pulposus during development and growth, with a shift toward a more chondrocyte-like cell population by age 7 (Meachim and Cornah, 1970; Taylor and Twomey, 1988; Trout *et al.*, 1982). Like all IVD regions, the nucleus pulposus contains multiple collagenous and noncollagenous proteins, including types III, V, VI, and IX collagens, elastin, fibronectin, and laminin (Hayes *et al.*, 2001; Oegema, 1993; Roberts *et al.*, 1991; J. Yu *et al.*, 2002). The nucleus pulposus is largely loaded in compression (Fig. 58.3) and experiences high interstitial swelling and fluid pressures, which arise from joint loading and a high density of osmotically active, proteoglycan-associated negative charges (Urban and McMullin, 1985, 1988). Nachemson and coworkers showed, as early as the 1960s, that this interstitial fluid pressure is greater than 0.5 MPa (or approximately five times atmospheric pressure) in the nucleus pulposus region (Andersson *et al.*, 1982; Nachemson, 1960, 1992). An early loss of hydration or tearing in the nucleus pulposus (Boos *et al.*, 2002), often detected as a loss of MR signal (Yu *et al.*, 1989), is believed to contribute to a loss of fluid pressurization in the IVD, which may lead to herniation or stenosis with aging (Buckwalter, 1995; McNally and Adams, 1992; Schultz *et al.*, 1982). With loss of fluid pressurization, the load distribution to the anulus fibrosus will shift from a characteristic outward “bulging” of the anulus to one of inward displacements (Adams *et al.*, 1996; Nachemson,

**FIG. 58.2.** Schema of different zones and microstructures comprising the intervertebral disc. Anulus fibrosus insets of macroscopic appearance and stained section illustrate the lamellar structure of the tissue. The lamellae comprise aligned collagen fiber bundles that are oriented with alternating angles of  $\pm 60^\circ$ . Nucleus pulposus insets of a stained section and scanning electron micrograph illustrate the randomly organized network of fine collagen fibers and gelatinous nature of the tissue. Circular inset contains a schema of building blocks for these cartilaginous tissues that include banded type I and type II collagen fibrils, aggrecan and smaller proteoglycans, water, and multiple ionic species.

**Table 58.1.** Ranges reported for compositional features and mechanical properties for nucleus pulposus and anulus fibrosus tissue regions of the nondegenerate intervertebral disc<sup>a</sup>

1992; Panjabi *et al.*, 1988; Shirazi-Adl, 1992). Partial or complete removal of the nucleus pulposus, occurring in some discectomy procedures, may lead to a loss of disc pressurization and disc height that will transfer loads to facet joints of the spine, increase segmental range of motion, and impact overall spinal stability. Restoration of this interstitial swelling pressure in the nucleus pulposus, or restoration of MR signal intensity, is an oft-cited criterion for restoration of a healthy functioning disc.

The anulus fibrosus is a lamellar, fibrocartilaginous structure that is highly organized into distinct lamellae (Coventry *et al.*, 1945a, 1945b) of highly oriented, and largely

type I collagen-containing fiber bundles (Cassidy *et al.*, 1989; Hickey and Hukins, 1980). Type II collagen concentration increases toward the innermost region of the anulus fibrosus as the concentration of type I collagen is diminished. As with the nucleus pulposus, the anulus fibrosus contains proteoglycans within the collagenous extracellular matrix, although at lesser concentrations, which vary from outer to inner regions of the tissue. The collagen reinforcement within the anulus fibrosus resists the tensile loads, which arise during physiological joint motions, and the swelling effects, which give rise to significant anular bulging and deformation. Consequently, the anulus fibrosus has a

**FIG. 58.3.** Axial compressive loading of the intervertebral disc gives rise to a radial deformation, or “outward bulge,” as the disc deforms in response to the compressive load. The high tensile stiffness of the healthy annulus fibrosus in the circumferential direction acts to restrict this outwardly directed deformation. Tissues of the disc will be variably loaded and experience a combination of compression, tension, and shear, as shown. Pressurization of the central and gelatinous nucleus pulposus is an important mechanism for load support and load transfer to the annulus fibrosus, which contributes to maintenance of disc height.

very high stiffness in tension, with moduli that vary with the angle of orientation along the principal collagen fiber direction (Table 58.1, Ebara *et al.*, 1996; Elliott and Setton, 2001; Fujita *et al.*, 1997; Galante, 1967; Holzapfel *et al.*, 2005; Skaggs *et al.*, 1994). Cells of the annulus fibrosus originate from the mesenchyme and exhibit many characteristics of fibroblasts and chondrocytes (Bayliss and Johnstone, 1992; Oegema, 2002; Postacchini *et al.*, 1984; Rufai *et al.*, 1995; Urban and Roberts, 1995). These cells are sparsely distributed in the mature IVD and exhibit very little intrinsic ability for self-repair. Disorders of the IVD that involve displacement or herniation of an IVD fragment are believed to arise from tears in the annulus fibrosus region, and discectomy procedures frequently involve removing a portion of this annulus tissue. Some tissue-engineering strategies are being developed around restoration of healthy annulus fibrosus function or composition, although the complexities of annulus structure and composition make this a very challenging goal.

The hyaline cartilage endplates of the IVD are important structures that transmit and distribute loads of the spinal column to the discs. Because of their direct contact with both the annulus fibrosus and the nucleus pulposus, the endplates are believed to be an important route of nutrient transport, particularly to cells of the nucleus pulposus (Antoniou *et al.*, 1996; Benneker *et al.*, 2005; Roberts *et al.*, 1996; Selard *et al.*, 2003; Urban *et al.*, 1977). With aging, the cartilage endplate will thin, as it undergoes mineralization and eventual replacement by bone. This mineralization of the endplate is thought to impede diffusion and nutrient flow to the disc, principally the nucleus pulposus, which is lacking in an alternate short-diffusion pathway. Endplate

changes, such as sclerosis, fracture, and modified vascularity, may be detected by MRI changes (Modic *et al.*, 1984) and are believed to contribute to symptomatic IVD degeneration (Bodguk, 1988; Kokkonen *et al.*, 2002; Weishaupt *et al.*, 2001). Thus, tissue-engineering strategies that preserve the health of the endplate without inducing additional damage are believed to be critical to restoring IVD function.

### III. BIOMATERIALS FOR NUCLEUS PULPOSUS REPLACEMENT

#### *In Situ* Hydrating Polymers

The development of biomaterials and cellular therapies for tissue-engineered IVD replacement has a long history but has not often progressed past preclinical evaluations. The complexity of the IVD, with its three distinct substructures and multiple pathologies, together with very harsh loading conditions and mechanical requirements, has led to challenges for engineering tissue replacements. The concept that nucleus pulposus changes are an important contributor to IVD disorders has led to an initial focus on the use of acellular biomaterials for restoration of the nucleus pulposus tissue or function (Carl *et al.*, 2004; Di Martino *et al.*, 2005; Klara and Ray, 2002). In this section, attention is given to strategies developed around the concept of using *in situ* hydrating, synthetic polymers to restore nucleus pulposus hydration and, consequently, IVD disc pressure and disc height. The device with the longest clinical history is based on a copolymeric hydrogel encased in a polyethylene-fiber jacket (polyacrylonitrile and polyacrylamide, PDN<sup>TM</sup>, Raymedica Inc., Fig. 58.4). When implanted in a desiccated state, the polymers absorb water while the polyethylene jacket restricts excessive swelling of the polymer. Similar concepts have been developed based on implantation of preformed devices constructed from semihydrated poly(vinyl) alcohol (Aquarelle<sup>TM</sup>, Stryker Spine Inc.), a copolymer of poly(vinyl alcohol) (PVA) and poly(vinyl pyrrolidone) (PVP) (Thomas *et al.*, 2003), or modified poly(acrylonitrile) reinforced by a Dacron mesh (Bertagnoli *et al.*, 2005, NeuDisc<sup>TM</sup>, Replication Medical). As shown for the PVA/PVP copolymeric implant (Fig. 58.5), the design goal is to exploit implant swelling pressure to restore the high compressive stiffness of the IVD, which is lost on dehydration or denucleation of the nucleus pulposus (Joshi *et al.*, 2006). The relevant stiffness is that measured after placement of the implant, with stiffness values reflecting both the material behaviors of the implant as well as the integration with the containing annulus fibrosus and endplates. An additional concept that has promoted development of these devices is an ability to maintain disc height.

As with many tissue replacements, there is a long list of requirements that must be satisfied for biomaterials to be used in this application, including the needs to achieve (1) favorable mechanical stiffness or mechanical properties matched to that of the native structure; in particular, the

**FIG. 58.4.** (left) Prosthetic disc nucleus (PDN, Raymedica), shown on the left, is composed of an *in situ* swelling synthetic polymer. The pellet is encased in a polyethylene jacket that restricts water imbibition, shown adjacent to the pellet. (right) The PDN is designed to fit into either the anterior portion of the vacated disc nucleus or the posterior portion. Shown is a schematic of placement of both anterior and posterior components within the nucleus pulposus disc space. Modified from Klara and Ray (2002) with permission.

**FIG. 58.5.** (top) Schematic of polymeric hydrogel implants placed within the contained space of the intervertebral disc. The compressive stiffness of the disc implant can be measured as the relationship between axial deformation and applied compressive load, as shown. (bottom) Stiffness values were obtained for an intact human motion segment (devoid of posterior elements). When denucleated, the stiffness drops significantly. Implantation of a copolymeric hydrogel of PVA/PVP is capable of restoring stiffness for the motion segment to intact values. Modified from Joshi *et al.* (2006) with permission.

compressive stresses generated must not exceed the failure strength of the adjacent endplate, in order to avoid endplate fracture or subsidence of the device, IVD height loss, and associated problems; (2) integration with adjacent structures in order to promote load transfer, minimize device migration or extrusion, and restore stability for the motion segment; (3) durability, or an ability to maintain physical support over millions of cycles of loading; (4) minimal gen-

eration of wear debris, if appropriate; and (5) standards of biocompatibility without eliciting systemic, cellular, or immunotoxicity. Some of the polymeric devices for nucleus pulposus replacement have experienced device extrusion, endplate failure, and endplate sclerosis after implantation. These observations are thought to relate to a mismatch in mechanical stiffness that leads to excessive endplate loading and poor integration associated with device migration (Boyd *et al.*, 2004; Huang *et al.*, 2005). Controlling interstitial hydration of the polymer is a desirable feature for this class of polymers in general, because excessive swelling can cause implant stiffness and endplate overloading.

### ***In Situ* Forming Polymers**

Injectable polymer systems, such as polymers that will undergo a physical transition to a gel-like or solidlike form via cross-linking or thermal or pH-induced transitioning, have been evaluated for placement into a vacant nucleus pulposus space (Bao and Yuan, 2002; Boyd *et al.*, 2004; Temenoff and Mikos, 2000; Thomas *et al.*, 2003). Many of the requirements for success of this strategy are similar to those just described, with the additional requirements that the polymers must exhibit minimal leaching during the *in situ* forming procedure and must provide the benefit of minimally invasive insertion into the disc space. *In situ* curing polyurethane is one widely studied *in situ* curing polymer that has been delivered to the disc space through an inflatable polyurethane balloon in order to contain excessive swelling.

Two alternative injectable polymers evaluated for nucleus pulposus replacement have been developed from cross-linkable biopolymers. The BioDisc™ (Cryolife) is composed of bovine serum albumin that is cross-linked via glutaraldehyde at the time of injection to form a mechanically stiff implant. Similarly, NuCore™ (SpineWave Inc.) is a protein hydrogel developed from a silk and elastin peptide-

containing sequence that is cross-linked via di-isocyanate at the time of injection (Boyd *et al.*, 2004). The cross-linking confers an extra stiffness to protein polymers, which is necessary to achieve satisfactory stiffness values for a disc implant. Both implant systems have been able to maintain disc stiffness and to restore disc height when implanted, providing evidence that successful integration is being achieved on injection. Furthermore, systems composed of native IVD polymers, such as the elastin peptide sequences, may confer some additional benefit as recognized components of the body. These approaches are promising as they move through clinical trials of implant feasibility in the current period.

#### IV. CELL-BIOMATERIAL CONSTRUCTS FOR IVD REGENERATION

A persistent limitation of materials-based replacements of the IVD is their biologically mediated or mechanically induced failure due to the harsh loading conditions and cellular responses within the disc space. These challenges are rooted in the fact that the materials used for such applications have no capacity for self-renewal or self-repair. This has led to increasing interest in tissue-engineering methods to regenerate new IVD *in situ* or to transplant IVD tissue that has been generated *ex vivo*. Such strategies have been employed to augment repair of other types of cartilage, most notably articular cartilage, and meniscus, which share some features of the harsh biologic and mechanical loading environment within the IVD.

##### Scaffolds for Cell-Based Tissue Engineering in the IVD

As in other cartilage-tissue-engineering applications, a main strategy for IVD regeneration has been the inclusion of cells with biomaterials to enable production and long-term maintenance of newly generated tissue. Biomaterials that enable appropriate cellular phenotypes and matrix biosynthesis and that sometimes enable polymeric degradation or resorption have been proposed as alternative implantable biomaterials and have been studied largely *in vitro*. The goals for use of these scaffolds are similar to those for other biomaterial implants, with the added requirements that the biomaterial must generate no cytotoxic or immunogenic degradation or breakdown fragments and that new matrix formation is enabled. Studies of cell-biomaterial constructs cultured *in vitro* have demonstrated potential for many materials (Table 58.2), including thermosensitive gels such as chitosan, modified chitosans, and elastinlike polypeptides (Au *et al.*, 2003; Betre *et al.*, 2002; Mwale *et al.*, 2005; Roughley *et al.*, 2006); self-associating gels composed of agarose, collagen, and fibrin (Gruber *et al.*, 2004; Peretti *et al.*, 2006); or modified forms of these same materials, cross-linkable alginates, polyethylene glycol, poly(glycolic acids), and more (Baer *et al.*, 2001; Burkoth and Anseth, 2000;

Elisseeff, 2004; Masuda *et al.*, 2003; Mercier *et al.*, 2004; Sontjens *et al.*, 2006). *In vitro* studies with these materials are based on evaluating new matrix formation and sometimes degradation characteristics through culturing native disc or other cell types within these matrices. Hydrogels, such as alginate and gelatin, have been used most commonly for engineering nucleus pulposus tissue, likely due to the fact that such materials reasonably approximate the gel-like properties of the native tissue. Cells of different origin, including native IVD cells, stem cells, and chondrocytes, are capable of synthesizing and depositing collagen and glycosaminoglycans within these hydrogels, although there is little agreement on the targeted composition necessary to achieve a satisfactory tissue construct. This is a particularly challenging determination for the IVD because the matrix contains varying amounts of both types I and II collagen, so the exclusive presence of type II collagen does not serve as a phenotypic matrix marker, as is the case for articular cartilage.

Efforts to regenerate annulus fibrosus have also involved gels such as alginate, agarose, gelatin, and collagen as well as fibers or sponges made from materials such as poly(glycolic) acid, collagen, hyaluronic acid, and/or glycosaminoglycans. Often, the same scaffolds evaluated for nucleus pulposus cells are also studied with cells of the annulus fibrosus, with findings that generally illustrate the importance of cell origin in determining the resultant extracellular matrix synthesis. A common observation, however, is that cells of either origin that are maintained in a rounded morphology tend to generate more type II collagen, characteristic of hyaline cartilage, whereas those that are cultured in an elongated morphology generate more type I collagen (Fig. 58.6). A main challenge has been reproducing the intricate lamellar arrangement of collagen fibers that give the annulus fibrosus its unique mechanical properties and the cells their unique morphology. For this reason, the majority of annulus-tissue-engineered materials have been generated from scaffolds that lack any apparent lamellar microstructure. Some investigators have developed polymeric scaffolds with anisotropic features, such as an oriented honeycomb structure, demonstrating production of multiple collagen types as well as proteoglycan (Sato *et al.*, 2003). These results are indeed suggestive of the potential to engineer anisotropic collagenous tissues, although no results for generating new, functional lamellar annulus tissue are known to exist to date.

Assessment of the success of IVD-tissue-engineering efforts is critical to moving this technology toward clinical application. Most studies have focused on generating new IVD *in vitro*, with few documenting tissue formation and integration in preclinical evaluations *in vivo*. To date, the most common tool for assessment of newly generated IVD tissue has been histology as a method to evaluate cell and tissue morphology. Given the structural complexity of the tissue, analysis of gene expression and extracellular matrix

composition has been commonly employed to confirm the appropriate phenotypic behavior in engineered IVD. Relatively few studies have documented mechanical analysis of engineered IVD tissue, but this will undoubtedly be critical as efforts to engineer functional tissue continue. Nevertheless, these *in vitro* studies begin to lay the foundation for necessary and/or sufficient characteristics of a successful scaffold for nucleus pulposus replacement. From these studies, for example, it is evident that a high starting cell density and a high degree of initial matrix stability are essential for promoting long-term construct stability and matrix accumulation, eventually to restore mechanical function and swelling pressure (Wilson *et al.*, 2002).

### Composite Cell-Biomaterial IVD Implants

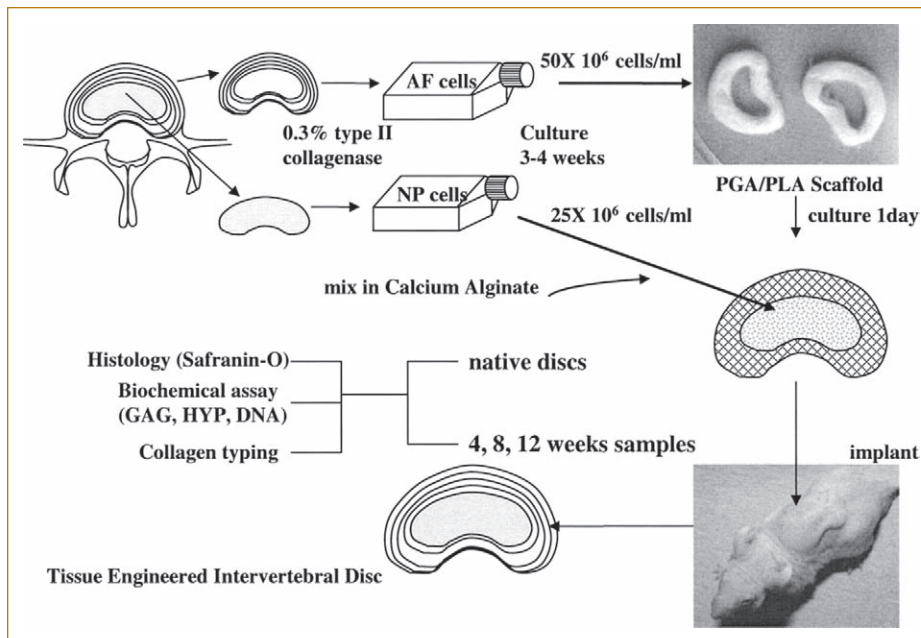

Cell-based regeneration of the IVD *ex vivo* is complicated by the inherent multicomponent structure of the IVD, which includes two distinct regions, the anulus fibrosus

and the nucleus pulposus. Given this added complication, it is not surprising that there are fewer examples of efforts to engineer integration of the multiple components of the IVD *ex vivo*. This can prove to be a critical limitation because integration is needed to ensure proper load transfer and to limit damaging motions during disc loading. In studies conducted by Bonassar and coworkers, IVD regeneration was attempted with a fully integrated scaffold combining poly(glycolic *co*-lactic acid) as a scaffold for anulus fibrosus and a cross-linked alginate hydrogel as a scaffold for nucleus pulposus tissue (Fig. 58.7) (Mizuno *et al.*, 2004, 2006). Primary cells for culture within each scaffold region were derived from the corresponding native IVD tissues, and the resultant cell-laden scaffolds were implanted subcutaneously into athymic mice for a period of 12 or 16 weeks. Results illustrate spatially directed matrix regeneration with extracellular matrix that exhibited distinct morphologies and contained both collagen and glycosaminoglycans (Fig.

**FIG. 58.6.** Top: (left) Annulus fibrosus cells are highly elongated in the outermost regions of the tissue but adopt a more rounded morphology in the inner tissue regions, as shown (middle). (right) When annulus fibrosus cells are embedded in an alginate hydrogel, they assume a rounded morphology. Bottom: Cells in alginate will express matrix proteins associated with chondrocytes, such as type II collagen and aggrecan. Bottom figure modified from Le Maitre *et al.* (2005) with permission.

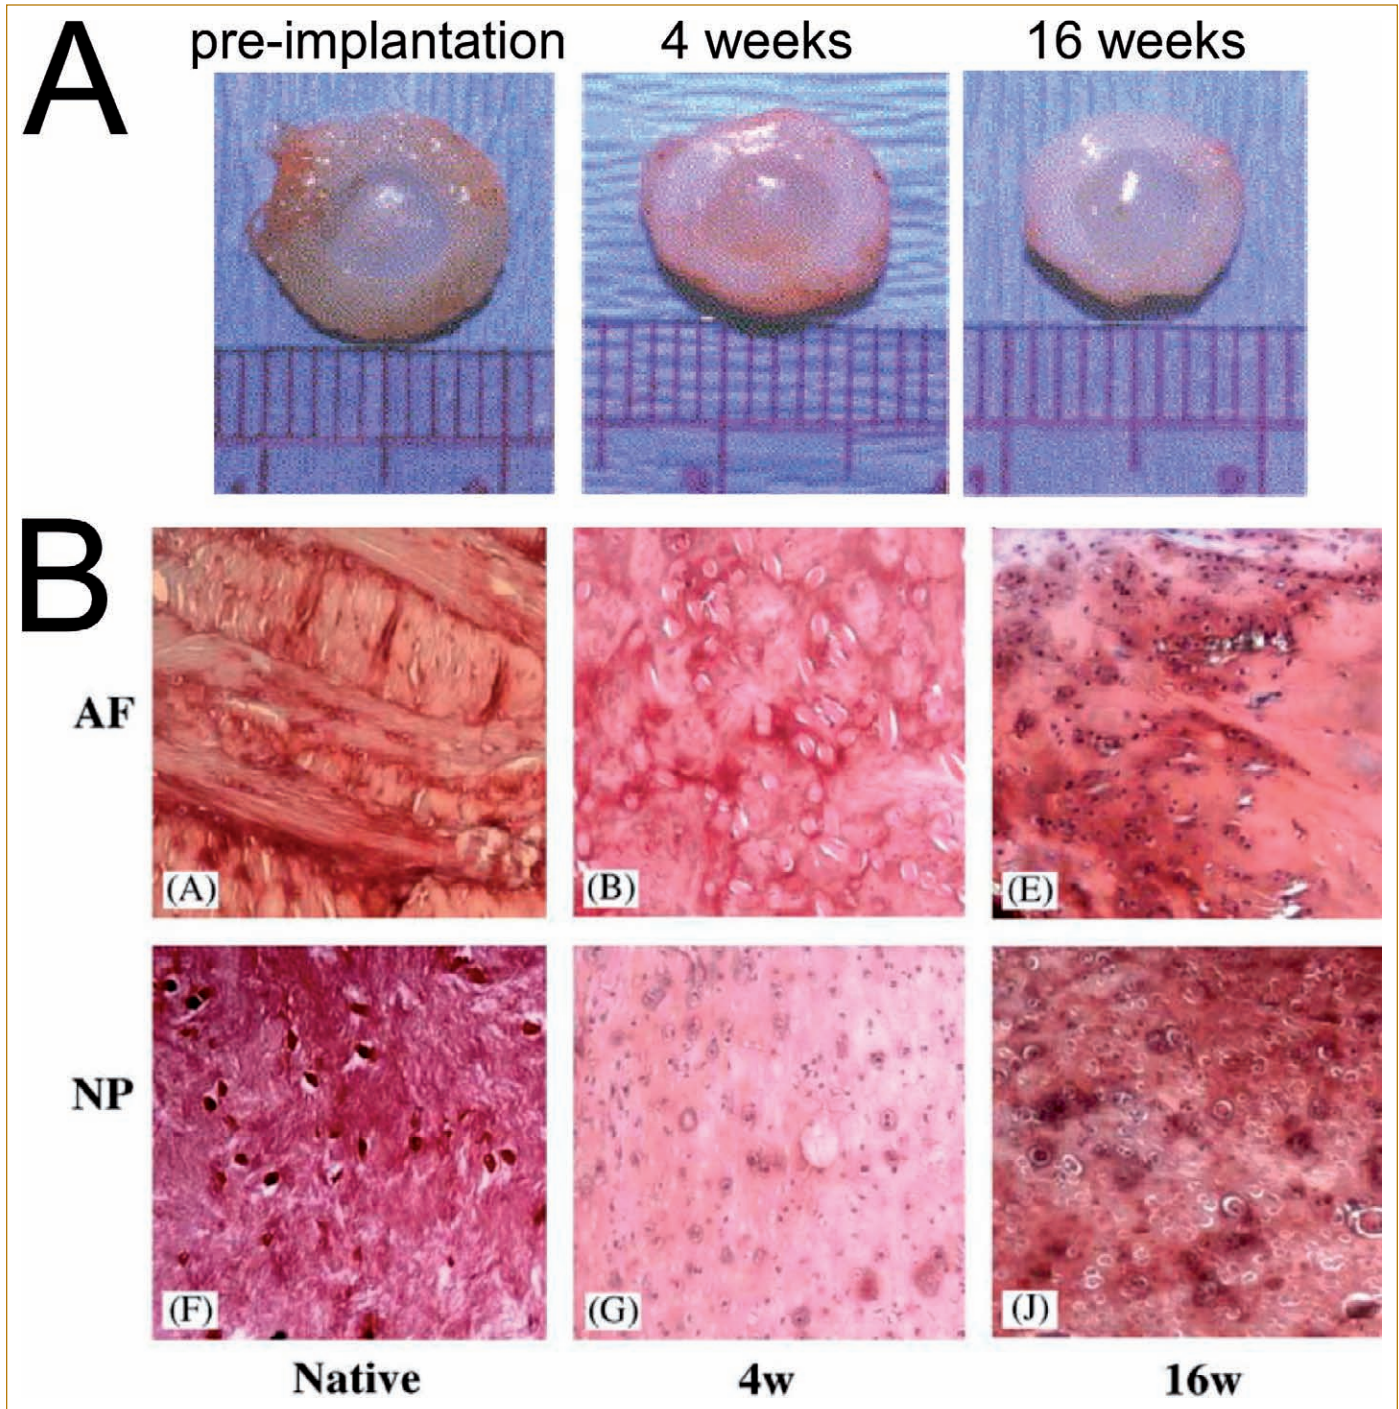

**FIG. 58.7.** Schema of tissue engineering for intervertebral discs. Annulus fibrosus and nucleus pulposus cells were isolated and cultured separately prior to seeding onto PGA/PLA scaffolds (annulus fibrosus) or suspension in a solution of 2% alginate (nucleus pulposus). The cell-alginate mixture was injected into the empty center of the PGA/PLA construct. The assembled tissue-engineered intervertebral disc constructs were implanted subcutaneously onto the dorsum of athymic mice and harvested at times up to 12 weeks. Reprinted with permission from Mizuno *et al.* (2004).

58.8). In biomechanical tests, the composite tissue-engineered disc was found to have a compressive modulus about one order of magnitude lower than that of the native tissue, with a permeability to fluid flow that fell between values for the nucleus pulposus and the annulus fibrosus. Thus, this approach illustrated an ability for cell-laden scaffolds to regenerate extracellular matrix with some of the functional and compositional features of the native tissue.

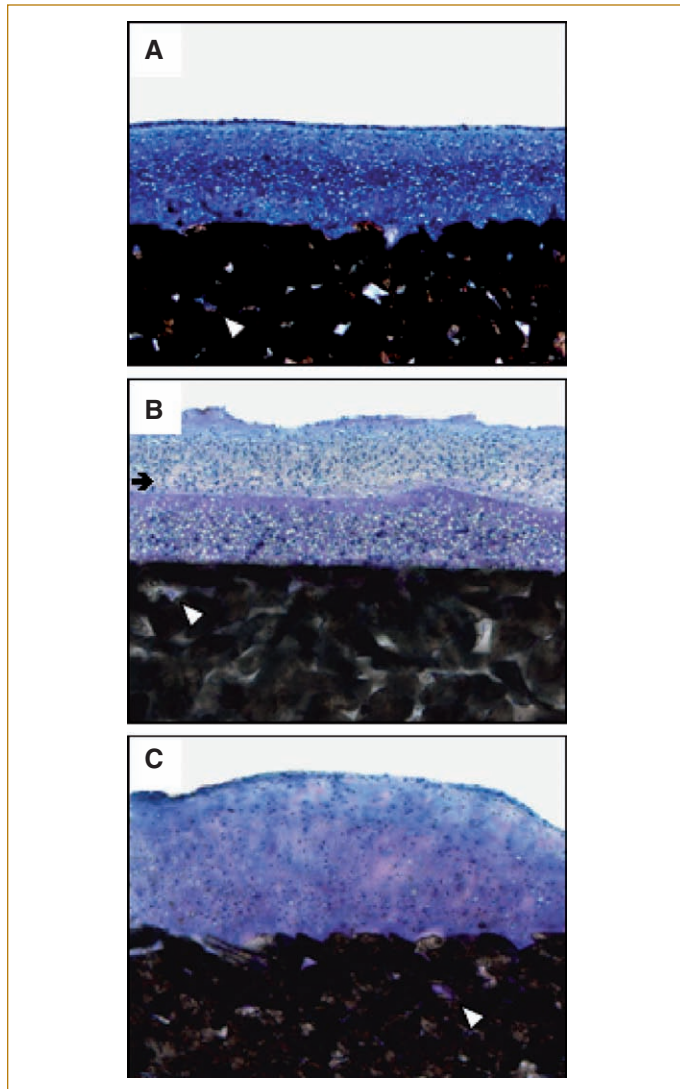

In another integrative tissue-engineering study of note, investigators Kandel and coworkers generated nucleus pulposus tissue *in vitro* by culturing primary bovine nucleus pulposus cells at high density on a calcium polyphosphate

substrate, in order to mimic the natural integration of the nucleus pulposus against the vertebral endplate (Fig. 58.9, Seguin *et al.*, 2004). A similar strategy was employed to generate a calcified tissue–cartilaginous endplate–nucleus pulposus construct by first generating a hyaline cartilage tissue layer on the calcium polyphosphate substrate prior to seeding with nucleus pulposus cells (Fig. 58.9 Hamilton *et al.*, 2006). The nucleus pulposus cells formed tissue with a proteoglycan, but not collagen content matched to that of the native nucleus pulposus. Importantly, functional properties in some testing configurations approached that of the native tissue. Additional work will be required in adapting

**FIG. 58.8.** (A) Gross morphology of tissue-engineered intervertebral disc constructs before implantation (*left*) and 16 weeks after implantation in the subcutaneous pouch of athymic mice. (B) Safranin O-stained sections of anulus fibrosus from (*left*) native ovine lumbar intervertebral disc and (*middle*) tissue-engineered intervertebral disc constructs at 4 weeks and (*right*) 16 weeks after implantation. these integrative tissue-engineering approaches to ensure that mechanical integration with adjacent tissues is adequate, but these studies focused on generating integrated nucleus-endplate or nucleus-anulus are an important step in illustrating feasibility for this approach.

## V. CELLULAR ENGINEERING FOR INTERVERTEBRAL DISC REGENERATION

Given the relatively small numbers of studies in the area of IVD-tissue engineering, there is a surprising amount of breadth not only to the biomaterials, but also to the cell sources utilized for regeneration. The question of cell source is of particular note for IVD-tissue engineering, given that the availability of autologous disc cells is extremely low in the adult and that the phenotype of cells varies so substantially with both spatial position and with age. In animals studied for IVD-tissue engineering *ex vivo*, the origin of cells in the nucleus pulposus may be partly notochordal or mesenchymal, depending on the age of the animal in question. As such, the choice of species used as a source of cells may be quite important. Due to the ease of availability, porcine and bovine cells are the most commonly used, with other efforts reporting the use of cells of canine, lapine, and ovine origin as well as human. However, cells derived from bovine tissues may be exclusively mesenchymal in origin, while those derived from porcine, lapine, or ovine sources may be largely notochordal. These phenotypic differences add an additional and unique complicating factor for investigators studying preclinical models for IVD-tissue regeneration.

Given the very limited availability of native IVD cells that can be effectively harvested for tissue engineering, there has been interest in using other cells as sources for these efforts. The primary target for other sources has been mesenchymal stem cells (MSCs) derived from sources such as bone marrow (Richardson *et al.*, 2006a) and adipose tissue (Li *et al.*, 2005). A major challenge in this approach has been the development of methods to guide the development of MSCs toward phenotypes found in the IVD (see next section). This has been attempted through manipulation of the culture medium and gas conditions (Risbud *et al.*, 2004) as well as through coculture with primary cells from the IVD (Richardson *et al.*, 2006b). In comparison to the use of adult primary disc cells derived from often-pathological or degenerated IVDs, the use of autologous or other MSCs or progenitor cells may be most promising to the future of *ex vivo* tissue-engineering strategies that rely on cell supplementation.

In addition to origin, cell density is known to have a profound effect on the efficacy of the tissue-engineering process. Here there has been a great deal of variability in protocols, with studies reporting densities of delivered cells ranging from  $0.2 \times 10^6$  to  $50 \times 10^6$  cells/mL. While the lower end of this scale is likely more reflective of the actual cell density in nucleus pulposus tissue, the densities at the higher end of the scale are more in line with those known to be effective in generating other types of cartilage (Puelacher *et al.*, 1994). A critical concern for disc-tissue regeneration, particularly in the case of strategies that employ high cell densities, is the issue of nutrient and gas supply necessary to maintain cell viability and health. The IVD is both avas-

cular and lymphatic, meaning that the transport of nutrients and oxygen is driven largely by diffusion from the vascularized periphery and through the vertebral endplates (Holm *et al.*, 1981; Maroudas *et al.*, 1975; Nachemson *et al.*, 1970; Stairmand *et al.*, 1991; Urban *et al.*, 1977). It is noteworthy that calcification and endplate changes in the degenerating IVD can lead to impaired nutrient transport, which is presumably linked to decreased cell viability (Benneker *et al.*, 2005; Roberts *et al.*, 1996). Thus, supplementation of scaffolds with very high cell densities may not be optimized for long-term survival in the largely hypoxic and glucose-poor, lactate-rich environment within the IVD. This concern has been expressed for cell-laden IVD scaffolds, but it has not been directly addressed or investigated as an issue in IVD-tissue regeneration.

### Cellular Supplementation in the IVD

If the local environment within the IVD is conducive to the survival of cells, direct cell supplementation without biomaterial scaffolds may hold promise for IVD repair. This strategy has been pursued by several groups, using either IVD cells, chondrocyte-like cells, or progenitor cells. In the first reported work, Nishimura and Mochida (1998) inserted nucleus pulposus cells from the rabbit, following removal of nucleus tissue, and showed some beneficial effects in inhibiting the degenerative IVD changes of nucleotomy. Similar procedures have also shown the effectiveness of autologous disc cell implantation in both a sand rat model of spontaneous disc degeneration (Gruber *et al.*, 2002) as well as a canine model of disc degeneration (Ganey *et al.*, 2003). Furthermore, work by Nomura and coworkers (2001) has shown that supplementation with allogeneic nucleus pulposus cells did not induce any appreciable host-versus-graft rejection response and also retarded disc degeneration in a rabbit nucleotomy model. It is noteworthy that nucleus pulposus cell insertion resulted in a slightly poorer outcome than did insertion of the allograft nucleus pulposus tissue itself, indicating that inclusion of the extracellular matrix present in the allograft may be as important as or more important than the absolute number of cells inserted (Nomura *et al.*, 2001).

Limitations will always exist in obtaining sufficient numbers of autologous or allogeneic disc cells from a single site, as well as concerns about impaired cellular activity for the native cells. Some studies have thus focused on using a coculture of nucleus pulposus and annulus fibrosus cells to stimulate cell metabolism prior to reinsertion (Okuma *et al.*, 2000). These approaches were shown to be effective in delaying some degenerative features, such as the loss of disc architecture following reinsertion of the activated cells in a rabbit model. Still other studies have focused on delivery of cells through allograft tissues based on the concept that preservation of extracellular matrix is an equally important criteria for regeneration (Matsumoto *et al.*, 2001a; Sato *et al.*, 2003; Seguin *et al.*, 2004; Yung Lee *et al.*, 2001).

Since 2002, a prospective, controlled, multicenter study has been performed to compare autologous disc cell transplantation plus discectomy against discectomy alone (Meisel *et al.*, 2006). The interim analysis of the first 28 patients at two years showed a clinically significant reduction of low-back pain in the transplantation group as compared to the discectomy group, suggesting a potential benefit of the cell transplantation strategies described earlier. Little is understood about the mechanism by which the cell supplementation provides this benefit, although disc hydration but not disc height was found to be higher in the patients receiving the cell transplantation as compared to the discectomy group. This clinical study underscores the role of autologous cell-mediated biological factors in regulating symptoms with IVD pathology and illustrates a potentially important role for sustaining cell viability of the IVD in inhibiting this pathology.

Clinically, the autologous reinsertion of the nucleus pulposus cells into the degenerative disc remains challenging (Evans, 2006). As a source of cells for transplantation, MSCs that can be harvested from a patient's own bone marrow are a possible candidate (Leung *et al.*, 2006; Risbud *et al.*, 2004; Sakai *et al.*, 2005). *In vitro*, the differentiation of MSCs into nucleus pulposus-like or chondrocyte-like cells has been shown under hypoxic and high-osmotic conditions (Risbud *et al.*, 2004) and also with TGF- $\beta$  stimulation (Steck *et al.*, 2005). Studies have followed injection of autologous MSCs embedded in atelocollagen gel as well as direct injection of MSCs into rabbit or rat models of IVD degeneration, and these have observed an ability for these cells to differentiate or regenerate matrix (Crevensten *et al.*, 2004; Sakai *et al.*, 2005, 2003). In one set of studies, transplantation of MSCs with an atelocollagen carrier into the rabbit discs effectively maintained disc height, MR signal intensity, and the histological appearance of the nucleus pulposus and annulus fibrosus regions at 24 weeks after transplantation (Fig. 58.10, Sakai *et al.*, 2003). Some of the positive outcomes observed for tissue regeneration in the animal models may arise from factors released from MSCs or direct contact with MSCs, which may enhance metabolism of native disc cells (Yamamoto *et al.*, 2004; Richardson *et al.*, 2006b).

Another approach to supplement cells without donor morbidity is the use of established cell lines, as shown recently following transplantation of a human nucleus pulposus cell line (Sakai *et al.*, 2005, 2004) into degenerated discs of the rabbit nucleotomy model (Iwashina *et al.*, 2006). Despite evidence that the cell supplementation was beneficial in retarding the progression of IVD degeneration, concerns about tumorigenesis and/or carcinogenesis associated with cell lines and the consequences of the use of a recombinant SV40 adenoviral vector need to be clarified before this strategy could be widely adopted. Given the increasing importance of MSCs and other progenitor cell therapies in articular-cartilage-, meniscus-, and other cartilage-regeneration strategies, expanded research on use of MSCs

**FIG. 58.10.** Rabbit IVDs were subjected to annular puncture as a model to induce IVD degeneration in a study by Sakai and coworkers. At two weeks after puncture, subsets of IVDs were transplanted with MSCs or left as sham-operated controls. **(A)** MRI of normal control (NC), sham (disc-degeneration model), and MSC-transplanted rabbits taken 26 weeks postinduction of degeneration (24 weeks after MSC transplantation). Significant recovery of T2-weighted signal intensity is seen in discs of MSC-transplanted discs as compared to very low signal intensity in sham. **(B)** Histological changes seen after MSC transplantation in discs. Control group discs show oval-shaped nucleus, with no collapse of the inner annular structure. Sham operated discs show collapse of the inner annulus morphology from four weeks (six weeks after induction of degeneration) and fibrotic changes in the nucleus pulposus completed by 24 weeks. MSC group discs showed relatively preserved inner annulus structure, with minimal fibrosis in the nucleus region. Bar = 200  $\mu$ m. Reprinted with permission from Sakai and coworkers (2006).

can be expected to comprise a significant effort in the future of IVD regeneration.

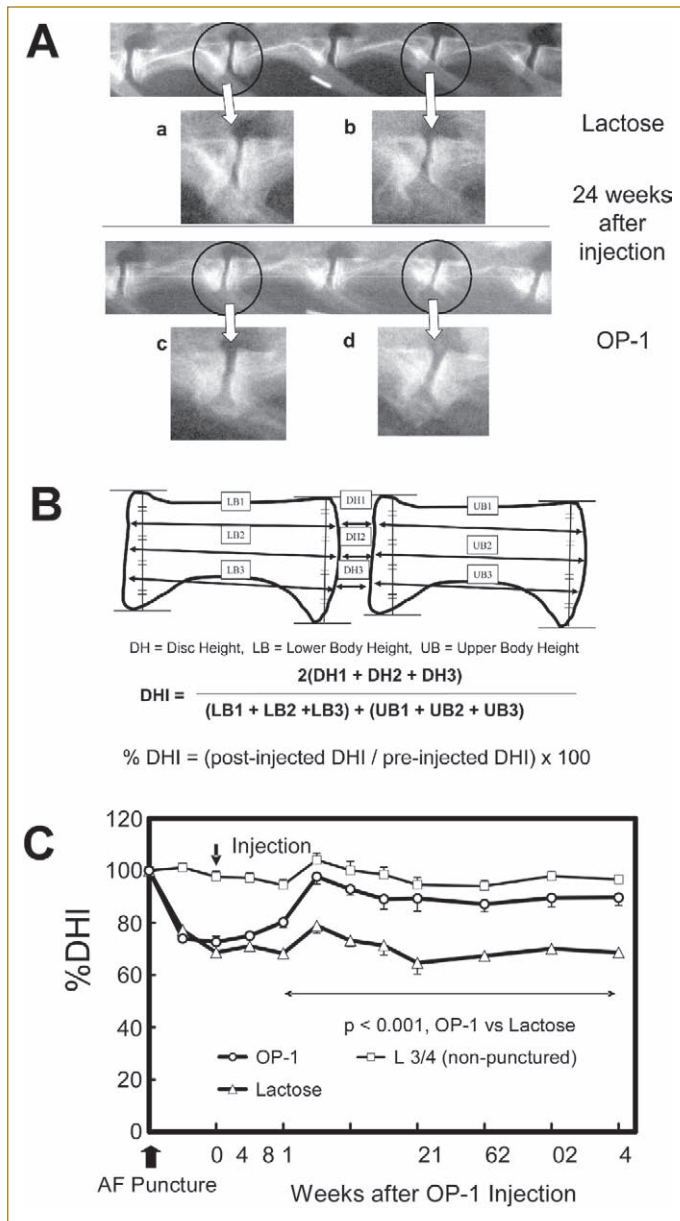

## VI. GROWTH FACTORS AND BIOLOGICS FOR INTERVERTEBRAL DISC REGENERATION

Disc cells modulate their activity by a variety of substances, including cytokines, growth factors, enzymes, and enzyme inhibitors, in a paracrine and/or autocrine fashion (Masuda and An, 2004). Tissue-engineering approaches to disc regeneration have been based on attempts to up-regulate important matrix proteins (e.g., aggrecan) or to down-regulate proinflammatory cytokines [e.g., interleukin-1 (IL-1), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ )] (Ahn *et al.*, 2002; Burke *et al.*, 2003; Igarashi *et al.*, 2000; Kang *et al.*, 1996; Le Maitre *et al.*, 2005; Olmarker and Larsson, 1998; Seguin *et al.*, 2005; Weiler *et al.*, 2005), and matrix-degrading enzymes (e.g., metalloproteinases and aggrecanases) (Evans, 2006; Le Maitre *et al.*, 2004; Roberts *et al.*, 2000; Sztrölovics *et al.*, 1997). Delivery of these modulating biologic agents, with and without scaffolds and/or through cell transplantation, has been the subject of many years of efforts in tissue engineering. *In vitro* studies have shown that the rate of matrix synthesis or gene expression for matrix proteins, principally proteoglycan or collagen, can be increased several-fold in IVD cells in the presence of supplemental transforming growth factor- $\beta$  (TGF- $\beta$ ), osteogenic protein-1 (OP-1) (Imai *et al.*, 2002; Masuda *et al.*, 2003), bone morphogenetic proteins (e.g., BMP-2) (Kim *et al.*, 2003; Tim Yoon *et al.*, 2003), growth and differentiation factor-5 (GDF-5) (Chujo *et al.*, in print; Li *et al.*, 2004), epidermal growth factor (EGF) (Gruber *et al.*, 1997; Thompson *et al.*, 1991), or insulinlike growth factor-1 (IGF-1) (Osada *et al.*, 1996). Other studies have demonstrated the potential of these growth factors as well as platelet-derived growth factor (PDGF) to reduce cell apoptosis and to promote cell proliferation (Gruber *et al.*, 1997, 2000). Autologous platelet-rich plasma, which contains a variable mixture of growth factors, has also been shown to be an effective stimulator of cell proliferation, proteoglycan and collagen synthesis, as well as proteoglycan accumulation, when added to IVD cell cultures *in vitro* (Akedo *et al.*, 2006). In a different approach, supplementation of IVD cell cultures with a naturally occurring antiinflammatory molecule, interleukin-1 receptor antagonist (rhIL-1Ra), has been shown to inhibit the down-regulation of biosynthesis induced by the proinflammatory cytokine, IL-1 (Akedo *et al.*, 2006; Pichika *et al.*, 2006). This illustrates that stimulatory factors as well as antiinflammatory or anticatabolic factors may be considered for therapeutic purposes in IVD regeneration. Overall, these *in vitro* studies have illustrated the potential for biologics to assist in matrix regeneration through controlling both cell metabolism and cell number, and they have paved the way for more recent studies evaluating these biologics *in vivo*.

Protein injection into the disc space is relatively simple and practical and has been the most widely studied of all approaches for delivery of biologics for IVD regeneration. Walsh and coworkers (2001) reported the *in vivo* effect of a single injection of several growth factors, including basic fibroblast growth factor (bFGF), GDF-5, IGF-1, or TGF- $\beta$ , in mouse caudal discs with degeneration induced by static compression. An increase in neomatrix was observed following the injection of GDF-5, while increases in the anulus fibrosus cell population were found under the influence of IGF-1 (Walsh *et al.*, 2002). In separate studies by Masuda and coworkers, a single intradiscal administration of rhOP-1 in normal rabbit discs *in vivo* was shown to result in increased disc height and proteoglycan content in the nucleus pulposus regions, in comparison to a saline injection control group (An *et al.*, 2005). In an animal model of disc degeneration caused by needle puncture of the anulus fibrosus, an injection of rhOP-1 (100  $\mu$ g/disc) restored disc height, structural change, and mechanical properties (Fig. 58.11) (Masuda *et al.*, 2006; Miyamoto *et al.*, 2006). The effectiveness of direct protein delivery was also confirmed in experiments using rhGDF-5, where a single injection of rhGDF-5 resulted in a restoration of disc height and improvements in MRI and histological grading scores in this same animal model of disc degeneration (Chujo *et al.*, 2006). These works are important for demonstrating that biologic manipulation of IVD cells *in vitro* may translate to an observed effect *in vivo* and that direct protein delivery may be useful for promoting new matrix formation in the absence of cell delivery. It is noteworthy that the latter studies using rhOP-1 and rhGDF-5 also provide documentation of pre-clinical measures, such as disc height, disc mechanics, and MRI appearance, that may be important for translating these technologies to noninvasive or minimally invasive clinical outcomes for patient treatment.

## VII. GENE THERAPY FOR INTERVERTEBRAL DISC REGENERATION

While the studies described earlier illustrate a range of proteins considered as possible therapies for IVD regeneration, it is important to consider the unavoidable limitations of protein delivery to the disc space. Issues such as protein half-life and solubility, the need for a proper carrier, the need to preserve mechanical environment or cell numbers, and/or the presence of inhibitors are all factors that can be expected to affect the therapeutic efficacy of protein delivery *in vivo*. A consideration for the use of recombinant protein therapies is also cost, because some disc pathologies and the need to inhibit disc degeneration may be chronic in nature or require multiple treatments. Gene therapy has been advocated as a therapeutic alternative for the delivery of biologics in disc regeneration (Nishida *et al.*, 1999; Wehling *et al.*, 1997; Yoon, 2005; Yoon *et al.*, 2004). DNAs that encode specific proteins may be delivered into

**FIG. 58.11.** IVDs of rabbit lumbar spines were subjected to annular puncture by an 18-gauge needle to induce disc degeneration. Four weeks after the initial puncture, the vehicle (5% lactose, 10  $\mu$ L) or OP-1 in 5% lactose (100  $\mu$ g/10  $\mu$ L at each level) was injected into the center of the nucleus pulposus. **(A, top)** Radiographs at the 24-week time after injection with lactose. **(A, bottom)** Radiographs of rabbit IVDs following injection with OP-1 in the experimental group, shown at 24 weeks after injection. **(B)** Method for radiographic measurement of disc height index (DHI). The average IVD height (DHI) was calculated by measurements obtained from the anterior, middle, and posterior portions and divided by the average of adjacent vertebral body heights. LBH indicates lower body height; UBH, upper body height. **(C)** Changes in % DHI after the annular puncture and OP-1 injections. As shown, % DHI of injected discs in the OP-1 group was significantly higher than in the lactose-injected control group by four weeks ( $p < 0.001$ , repeated ANOVA). This difference in % DHI was maintained out to later periods.

the cells by viral or nonviral transfection, with the result that these cells produce proteins to, theoretically, prolong the duration of action. The first successful attempt for *in vitro* gene transfer was reported for chondrocyte-like cells from the endplate of the IVD using a retroviral-mediated technique (Wehling *et al.*, 1997). An *ex vivo* approach was used based on harvesting host cells, infecting these host cells *in vitro*, selecting and enriching infected cells, and finally returning these cells to the host. This approach avoids problems associated with low cell numbers and transfection efficiencies, but it is both challenging and costly to perform. Nevertheless, because a decrease of cells by apoptosis or necrosis is considered to be associated with advanced disc degeneration, cell supplementation with genetically manipulated cells will continue to hold promise for disc regeneration.

Adenoviral vectors often possess high titers and infectivity and are able to infect nondividing cells such as IVD cells. Adenoviral-mediated gene transfer to human IVD cells has been shown to be efficient and to produce transcripts across nondegenerative to degenerative cell types, using adenovirus carrying lacZ (Ad/CMV-lacZ) or luciferase marker genes (Ad/CMV-luciferase) as well as Sox9 (Ad/Sox9-GFP), GDF-5, and TGF- $\beta$ 1 adenoviral constructs (Moon *et al.*, 2000; Wang *et al.*, 2004; Paul *et al.*, 2003). Yoon and coworkers (2004) also used adenoviral vector to transfer LIM mineralization protein-1 (LMP-1) to rat IVD cells *in vitro* and observed an increase of BMP-2 and BMP-7 gene expression and protein production, and proteoglycan synthesis. The feasibility of using direct *in vivo* adenoviral-mediated gene transfer to disc cells has also been demonstrated using the lacZ, TGF- $\beta$ , LMP-1, and Sox9 genes (Moon *et al.*, 2000; Nishida *et al.*, 1998; Yoon *et al.*, 2004), finding transgene expression to be present or to exert a biological effect on biosynthesis, often for several weeks.

In addition to up-regulation of anabolic factors, inhibition of catabolic processes has been studied using gene therapy for IVD regeneration. Wallach and coworkers (2003) reported that gene transfer of the tissue inhibitor of metalloproteinase-1 (TIMP-1), an inhibitor of catabolic enzymes, can increase proteoglycan accumulation within pellet cultures of human IVD cells. LeMaitre recently reported that human disc cells infected with Ad-IL-1 receptor antagonist (Ad/IL-1Ra) were resistant to IL-1 (Le Maitre *et al.*, 2006). When *in vitro* infected cells were injected into disc explants *in vitro*, IL-1 receptor antagonist protein expression was also increased and maintained for the two-week time period investigated.

There are significant concerns about adenoviral vector use clinically, however, which may include significant toxicity when used in spinal applications (Driesse *et al.*, 2000; Wallach *et al.*, 2006). These concerns have led investigators to begin consideration of adeno-associated viral vectors (Lattermann *et al.*, 2005) and baculoviral vectors, the latter of which may be nontoxic (Liu *et al.*, 2006). Both

approaches may provide safe alternatives for future disc therapies, although much work remains. Also, to avoid safety concerns found with viral gene transfer, several nonviral methods for direct gene transfer to cells have been proposed. Preliminary reports using microbubble-enhanced ultrasound gene therapy (Nishida *et al.*, 2006) and a “gene-gun” method (Chang *et al.*, 2000; Matsumoto *et al.*, 2001b) have shown that introduction of a marker or growth factor gene could be accomplished and provide sustained gene expression without the need for viral vectors. Transfection efficacy with nonviral means is lower, however, than that in viral transfection, and further investigation will be needed to apply these in a clinical setting. Nevertheless, both viral and nonviral transfection methods have pros and cons. Safety and immunological reactions as well as the control of expression in viral-mediated gene therapy are potential problems. The comparatively low immunologic exposure of the healthy disc and its low cellularity seem to suggest that safety with gene delivery of therapeutic agents is a lesser concern in the IVD. Cells are needed to transduce the biological effect, however, so transplantation of *ex vivo* transfected cells may be an important part of the future potential for gene therapy in the IVD. During this time, work continues on identification of broader and more diverse molecular targets that can be useful for gene delivery in the treatment of IVD regeneration.

## VIII. CONCLUDING REMARKS

Efforts to regenerate and replace the tissues of the intervertebral disc have virtually exploded over the last two decades, although the field remains in its infancy. The complexity of the diverse degenerative and pathological processes that affect the IVD as well as the intrinsic complexity of the heterogeneous disc structures demand that multiple

strategies be developed for treatment of the IVD. Partial IVD replacements using acellular, preformed, or *in situ*-formed biomaterials have the longest history of development and are important for defining procedural outcomes that will be relevant to long-term functional success. Development of strategies using cells, biologics, or gene therapy is often focused on the restoration of a single tissue source, such as nucleus pulposus or anulus fibrosus, and with or without biomaterial scaffolds. Only a few tissue-engineering solutions have been proposed to integrate two dissimilar tissues in the repair process, and additional work to promote integration among native, neogenerated, and implanted tissues will be critical to restoring IVD function. Many of the identified strategies derive largely from knowledge gained in cartilage-tissue engineering, although the differing cellular, functional, and structural requirements of the IVD suggest that custom approaches are needed. Advances in IVD cell biology are needed to enable the identification of novel therapeutic targets, to select for classes of biomaterials, and to suggest appropriate drug delivery strategies, for disc cell phenotype, cell-biomaterial interactions, and the biology of aging for these cells are still poorly understood. While a diverse array of molecules, cell sources, and materials is suggested as appropriate for IVD regeneration, additional work is needed to reveal some common and unique themes in human IVD cell responses that focus research on IVD-specific strategies. Currently underway clinical trials of autologous cell therapies or autologous protein products will pave the way for later generations of cellular and biologic-based therapies, because they are expected to illustrate the unique challenges of treating the pathologic and aged human IVD. The next decade promises great advances in the translation of basic and applied sciences to the clinical treatment of IVD regeneration and replacement.

### I. INTRODUCTION

In an effort to decrease the risk of posttraumatic osteoarthritis, surgeons and scientists have been seeking ways to prevent progressive joint degeneration following injury. Surgeons have used operative treatments, including penetrating subchondral bone, soft-tissue grafts, and cell transplants, to stimulate restoration of damaged articular surfaces, with variable results. This chapter covers recent work suggesting that several biologic agents, including caspase inhibitors and antioxidants, may minimize mechanical damage to chondrocytes and experimental studies indicating that use of artificial matrices, growth factors, and immature chondrocytes or stem cells may promote formation of a new joint surface.

Mechanical loading of articular surfaces that exceeds the tolerance of those surfaces damages chondrocytes and their matrix, damage that can cause joint degeneration leading to the clinical syndrome of posttraumatic osteoarthritis. The risk of posttraumatic osteoarthritis depends on the type and severity of the injury and also on the repair and remodeling of the damaged articular surfaces. Three classes of joint injuries can be identified, based on the type of articular surface damage: (1) chondral damage and in some cases subchondral bone damage that does not cause visible disruption of the articular cartilage, (2) mechanical disruption of the joint surface limited to articular cartilage (chondral ruptures or tears), and (3) mechanical disruption of

articular cartilage and subchondral bone (articular surface fractures). In most instances, chondrocytes can repair damage that does not disrupt the articular surface if they are protected from further injury. Mechanical disruption of articular cartilage stimulates chondrocyte synthetic activity, but this response, with few if any exceptions, fails to repair the tissue damage. Disruption of articular cartilage and subchondral bone stimulates chondral and bony repair. The osteochondral repair response usually heals the bony injury, but the chondral repair tissue does not duplicate the properties of normal articular cartilage.

Normal pain-free movement depends on the unique properties of the articular cartilage that forms the bearing surfaces of synovial joints (Buckwalter and Mankin, 1997). Degeneration of this remarkable tissue causes osteoarthritis: joint pain and dysfunction that limits mobility (Buckwalter *et al.*, 2000, 2005). The mechanisms, frequency, and natural history of articular-surface injuries are poorly understood, but it is clear that these injuries can lead to posttraumatic osteoarthritis (Buckwalter, 1992, 1995, 2002; Buckwalter and Mankin, 1997). Limited awareness of chondral and osteochondral injuries and difficulty in diagnosing these injuries makes it impossible to determine accurately their incidence or their relationship to the development of joint degeneration (Buckwalter and Lane, 1996, 1997; Buckwalter and Mankin, 1997). However, arthroscopic examinations of injured knee joints suggest

that closed articular-surface injuries occur frequently (Noyes *et al.*, 1980; Noyes and Stabler, 1989). One group of surgeons examined arthroscopically 85 knees with traumatic hemarthrosis but absent or negligible ligamentous instability (Noyes *et al.*, 1980). Twenty percent of these knees had articular-surface defects. In many patients cartilage injuries occur in association with injuries to other joint tissues, including menisci, ligaments, joint capsule, and synovium. In these people the cartilage injury may be overlooked; even when it is identified it is difficult to distinguish the effects of the cartilage injury from the effects of the injuries to the other tissues. Damage to articular surfaces that does not result in visible disruption of articular cartilage or subchondral bone is not easily detected, although it probably occurs far more frequently than chondral and osteochondral fractures (Buckwalter, 1992, 2002).

Recent advances in methods of diagnosing articular-surface injuries, including arthroscopy and magnetic resonance imaging (Spindler *et al.*, 1993; D. L. Johnson *et al.*, 1998b; Rubin *et al.*, 2000), combined with reports of new methods of stimulating cartilage repair or regeneration and osteochondral transplantation have increased interest in these injuries. Clinical evaluation of patients with articular-surface damage and determining the appropriate role of these new treatments or the need for any treatment requires an understanding of the mechanisms of these injuries and their natural history. This chapter discusses the relationship between articular-surface injury and joint degeneration, mechanisms of articular-surface injuries, the responses of articular surfaces to injury, and approaches to preventing joint degeneration following joint injury.

## II. ARTICULAR-CARTILAGE INJURY AND JOINT DEGENERATION

The end stage of posttraumatic osteoarthritis, the osteoarthritis that follows joint injury, is identical to that of primary osteoarthritis, but patients with posttraumatic osteoarthritis are often young or middle-aged adults and have a well-defined precipitating insult (Gelber *et al.*, 2000; Buckwalter and Brown, 2004). Clinical experience and epidemiologic studies show that meniscal, ligament, and joint-capsule tears, joint dislocations, and intraarticular fractures increase the risk of the progressive joint degeneration that causes posttraumatic osteoarthritis (Gelber *et al.*, 2000; Marsh *et al.*, 2002; Nelson *et al.*, 2006). Participation in sports that expose joints to high levels of impact or torsional loading also increases the risk of joint degeneration (Buckwalter and Lane, 1997; Buckwalter and Brown, 2004).

The risk of osteoarthritis following joint injury varies with the type of injury: Meniscal and ligamentous injuries have a lower risk than intraarticular fractures. Gelber *et al.* (2000) found that 13.9% of those who had a knee injury (including meniscal, ligamentous, or bone injuries) during adolescence or young adulthood developed knee osteoarthritis, as compared with 6.0% of those who did not have a

knee injury. A study of patients who suffered ligamentous and meniscal injuries of the knee reported that they had a tenfold increased risk of osteoarthritis as compared with patients who do not have joint injury (Gillquist and Messner, 1999). Intraarticular fractures have the greatest risk of osteoarthritis. Depending on the severity of the injury and on the joint, the risk ranges from about 25% to more than 50% of patients (Marsh *et al.*, 2002; Buckwalter and Brown, 2004).

The time interval between joint injury and the development of osteoarthritis varies from less than a year in patients with severe intraarticular fractures to a decade or more in some patients with ligamentous or meniscal injuries (Marsh *et al.*, 2002; Buckwalter and Brown, 2004). Because many joint injuries occur in young adults, the population of patients with posttraumatic osteoarthritis includes many individuals under 50 years of age. But older individuals may have an increased risk of osteoarthritis after joint injuries. Studies of patients with intraarticular fractures of the knee show that patients older than 50 years of age have a twofold-to-fourfold greater risk of developing osteoarthritis than younger patients; patients over 40 years who have acetabular fractures and patients over 50 years who have displaced ankle fractures may also have a greater risk of OA than younger patients who have similar injuries; and age increases the risk of knee-joint degeneration after anterior cruciate ligament injury (Buckwalter and Brown, 2004; Buckwalter *et al.*, 2004).

## III. MECHANISMS OF ARTICULAR-CARTILAGE INJURIES

Understanding the mechanisms of articular surface injuries requires appreciation of how loads and rate of loading affect articular cartilage (Buckwalter, 2002; Martin *et al.*, 2004). Slowly applied loads and suddenly applied loads differ considerably in their effects. The articular-cartilage extracellular matrix consists of water and a macromolecular framework formed primarily by collagens and large aggregating proteoglycans (Buckwalter and Mankin, 1997). The collagens give the tissue its form and tensile strength, and the interaction of aggregating proteoglycans with water gives the tissue its stiffness to compression, resilience, and probably its durability. Loading of articular surfaces causes movement of fluid within the articular-cartilage matrix that dampens and distributes loads within the cartilage and to the subchondral bone (Mow and Rosenwasser, 1988). When this occurs slowly, the fluid movement allows the cartilage to deform and decreases the force applied to the matrix macromolecular framework. When it occurs too rapidly for fluid movement through the matrix and deformation of the tissue, as with sudden impact or torsional joint loading of the joint surface, the matrix macromolecular framework sustains a greater share of the force. If this force is great enough, it ruptures the matrix macromolecular framework, damages cells, and exceeds the ability of

articular cartilage to prevent subchondral-bone damage by dampening and distributing loads.

*In vivo*, expected and unexpected and slow and sudden movements or impacts may differ in the amount of force transmitted to joint surfaces. Muscle contractions absorb much of the energy and stabilize joints during slow, expected movements or impacts. Sudden or unexpected movements or impacts may occur too rapidly for muscle contractions to stabilize joints and decrease the forces on the articular surfaces. For this reason, sudden and unexpected movements or impacts can transmit greater forces to joint surfaces.

Acute or repetitive blunt joint trauma can damage articular cartilage and the calcified cartilage zone–subchondral-bone region while leaving the articular surface intact (Donohue *et al.*, 1983; Thompson *et al.*, 1991; Buckwalter, 1992; Zang *et al.*, 1999; Loening *et al.*, 2000). The intensity and type of joint loading that can cause chondral and subchondral damage without visible tissue disruption has not been well defined. Physiologic levels of joint loading do not appear to cause joint injury, but impact loading above that associated with normal activities but less than that necessary to produce cartilage disruption can cause alterations of the cartilage matrix and damage chondrocytes (Donohue *et al.*, 1983; Thompson *et al.*, 1991; Buckwalter, 1992; Jeffrey *et al.*, 1995, 1997; Loening *et al.*, 2000). Experimental evidence shows that loss of proteoglycans or alteration of their organization (in particular, a decrease in proteoglycan aggregation) occurs before other signs of cartilage injury following impact loading. The loss of proteoglycans may be due either to increased degradation of the molecules or to decreased synthesis. Significant loss of matrix proteoglycans decreases cartilage stiffness and increases its permeability. These alterations may cause greater loading of the remaining macromolecular framework, including the collagen fibrils, increasing the vulnerability of the tissue to further damage from loading. These injuries may cause other matrix abnormalities besides loss of proteoglycans, such as distortions of the collagen fibril meshwork and disruptions of the collagen fibril proteoglycan relationships and swelling of the matrix (Donohue *et al.*, 1983), and they may injure chondrocytes (Buckwalter, 1992; Loening *et al.*, 2000).

Currently there is no clinically applicable method of detecting alterations in cartilage matrix composition such as decreased proteoglycan concentration and increased water concentration; however, new imaging techniques may provide methods of assessing articular-cartilage composition. When probing the articular surface, surgeons sometimes find regions of apparent softening that may result from alterations in the matrix, and devices are being developed that will allow *in vivo* measurement of articular-surface stiffness. Combined with information about cartilage composition, these measurements may make it possible to better define injuries to the articular surface that do not result in visible tissue disruption.

Disrupting a normal articular surface with a single impact requires substantial force, presumably because of

the ability of articular cartilage and subchondral bone to dampen and distribute loads. A transarticular load of 2170 newtons applied to canine patellofemoral joints caused fractures in the zone of calcified cartilage visible by light microscopy and articular cartilage fissures that extended from the articular surface to the transitional or superficial radial zone of the articular cartilage (Thompson *et al.*, 1991). A study of the response of human articular cartilage to blunt trauma showed that articular cartilage could withstand impact loads of up to 25 newtons per square millimeter (25 MPa) without apparent damage. Impact loads exceeding this level caused chondrocyte death and cartilage fissures (Repo and Finlay, 1977). The authors suggested that reaching a stress level that could cause cartilage damage required a force greater than that necessary to fracture the femur. Another study (Haut, 1989) measured the pressure on human patellofemoral articular cartilage during impact loading and found that impact loads less than the level necessary to fracture bone caused stresses greater than 25 MPa in some regions of the articular surface. With the knee flexed 90°, 50% of the load necessary to cause a bone fracture produced joint pressures greater than 25 MPa for nearly 20% of the patellofemoral joint. At 70% of the bone fracture load, nearly 35% of the contact area of the patellofemoral joint pressures exceeded 25 MPa, and at 100% of the bone fracture load 60% of the patellofemoral joint pressures exceeded 25 MPa. These latter results show that impact loads can disrupt cartilage without fracturing bone.

Other experimental investigations show that repetitive impact loads split articular-cartilage matrix and initiate progressive cartilage degeneration (Weightman *et al.*, 1973; Weightman, 1976; Dekel and Weissman, 1978). Cyclic loading of human cartilage samples *in vitro* caused surface fibrillation (Weightman, 1976), and periodic impact loading of bovine metacarpal phalangeal joints *in vitro* combined with joint motion caused degeneration of articular cartilage (Radin and Paul, 1971). Repeated overuse of rabbit joints *in vivo* combined with peak overloading caused articular cartilage damage, including formation of chondrocyte clusters, fibrillation of the matrix, thickening of subchondral bone, and penetration of subchondral capillaries into the calcified zone of articular cartilage (Dekel and Weissman, 1978). The extent of cartilage damage appeared to increase with longer periods of repetitive overloading, and deterioration of the cartilage continued following cessation of excessive loading. This latter finding suggests that some cartilage damage is not immediately visible.

An investigation of cartilage plugs also showed that repetitive loading disrupted the tissue and that the severity of the damage increased with increasing load and increasing number of loading cycles (Zimmerman *et al.*, 1988). Two hundred and fifty cycles of a 1000-pound-per-square-inch compression load caused surface abrasions. Five hundred cycles produced primary fissures penetrating to calcified cartilage, and 1000 cycles produced secondary fissures extending from the primary fissures. After 8000 cycles, the

fissures coalesced and undermined cartilage fragments. Higher loads caused similar changes with fewer cycles. The experiments suggested that repetitive loading can propagate vertical cartilage fissures from the joint surface to calcified cartilage and cause extension of oblique fissures into areas of intact cartilage.

Clinical studies have identified articular-cartilage fissures, flaps, and free fragments and changes in subchondral bone similar to those produced experimentally by single and repetitive impact loads (Buckwalter, 1992; Levy *et al.*, 1996). In at least some patients, acute impact loading of the articular surface or twisting movements of the joint apparently caused these injuries. In other patients, the cartilage damage may have resulted from repetitive loading. Magnetic resonance imaging of joints soon after an acute impact or torsional load occasionally shows changes in subchondral bone consistent with damage to the zone of calcified cartilage and subchondral bone, even when the articular surface is intact (Vellet *et al.*, 1991; Spindler *et al.*, 1993; D. L. Johnson *et al.*, 1998; Rubin *et al.*, 2000).

Clinical experience suggests that chondral ruptures or tears and osteochondral fractures result from similar impact and twisting-joint injuries, but they tend to occur in different age groups, and some individuals may have a greater risk of chondral tears. Chondral tears generally occur in skeletally mature people, while osteochondral fractures typically occur in skeletally immature people or young adults. This difference may result from age-related changes in the mechanical properties of the articular surface, including the uncalcified cartilage, the calcified cartilage zone, and the subchondral bone. That is, age-related alterations in the articular-cartilage matrix decrease the tensile stiffness and strength of the superficial zone; and the calcified cartilage zone subchondral bone region mineralizes fully following completion of skeletal growth, presumably creating a marked difference in mechanical properties between the uncalcified cartilage and the calcified cartilage subchondral bone region. Taken together these changes probably increase the risk of ruptures of the superficial-cartilage matrix and of these ruptures extending to the calcified cartilage subchondral bone region. Genetically determined abnormalities of the articular cartilage may also increase the risk of chondral ruptures from a given impact or torsional load, but the relationships between known genetic abnormalities of articular cartilage and cartilage properties have not been well defined.

#### IV. RESPONSE OF ARTICULAR CARTILAGE TO INJURY

Articular-surface injuries can be classified based on the type of tissue damage and the repair response: (1) cartilage matrix and cell injuries, that is, damage to the joint surface that does not cause visible mechanical disruption of the articular surface; (2) chondral fissures; flap tears, or chon-

dral defects, that is, visible mechanical disruption of articular cartilage limited to articular cartilage; and (3) osteochondral injuries, that is, visible mechanical disruption of articular cartilage and bone (Buckwalter *et al.*, 1988b, 1990, 2003; Buckwalter, 1992; Buckwalter and Mankin, 1997) (Table 59.1).

#### Matrix and Cell Injuries

Acute or repetitive blunt trauma, including excessive impact loading, can cause alterations in the articular-cartilage matrix, including a decrease in proteoglycan concentration and possibly disruptions of the collagen fibrillar framework. Injuries that do not cause an apparent articular-cartilage injury, including joint dislocations or ligament and joint capsule tears, may have associated damage to the articular-cartilage cells and matrix (Tiderius *et al.*, 2005). The ability of chondrocytes to sense changes in matrix composition and to synthesize new molecules makes it possible for them to repair damage to the macromolecular framework (Martin and Buckwalter, 2000). It is not clear at what point this type of injury becomes irreversible and leads to progressive loss of articular cartilage. Presumably, the chondrocytes can restore the matrix as long as the loss of matrix proteoglycan does not exceed what the cells can rapidly produce, if the fibrillar collagen meshwork remains intact, and if enough chondrocytes remain viable. When these conditions are not met, the cells cannot restore the matrix, the chondrocytes will be exposed to excessive loads, and the tissue will degenerate.

#### Chondral Injuries

Acute or repetitive trauma can cause focal mechanical disruption of articular cartilage, including fissures, chondral flaps or tears, and loss of a segment of articular cartilage (Buckwalter, 1992). The lack of blood vessels and lack of cells that can repair significant tissue defects limit the response of cartilage to injury (Buckwalter *et al.*, 1990; Buckwalter and Mow, 1992). Chondrocytes respond to tissue injury by proliferating and increasing the synthesis of matrix macromolecules near the injury. But the newly synthesized matrix and proliferating cells do not fill the tissue defect, and soon after injury the increased proliferative and synthetic activity ceases.

#### Osteochondral Injuries

Unlike injuries limited to cartilage, injuries that extend into subchondral bone cause hemorrhage and fibrin clot formation and activate the inflammatory response (Buckwalter *et al.*, 1990, 2003; Buckwalter and Mow, 1992). Soon after injury, blood escaping from the damaged-bone blood vessels forms a hematoma that temporarily fills the injury site. Fibrin forms within the hematoma and platelets bind to fibrillar collagen. A continuous fibrin clot fills the bone defect and extends for a variable distance into the

**Table 59.1. Chondral and osteochondral injuries**

<i>Injury</i>	<i>Clinical presentation</i>	<i>Repair response</i>	<i>Potential for healing</i>
Damage to chondral matrix and/or cells and/or subchondral bone without visible disruption of the articular surface	No known symptoms, although subchondral-bone injury may cause pain  Inspection of the articular surface and current clinical imaging methods for articular cartilage cannot detect this type of injury  Imaging of subchondral bone may show abnormalities	Synthesis of new matrix macromolecules  Cell proliferation?	If the basic matrix structure remains intact and enough viable cells remain, the cells can restore the normal tissue composition  If the matrix and/or cell population sustains significant damage or if the tissue sustains further damage, the lesion may progress to cartilage degeneration
Cartilage disruption (chondral fractures or ruptures)	May cause mechanical symptoms, synovitis, pain, and joint effusions	No fibrin clot formation or inflammation  Synthesis of new matrix macromolecules and cell proliferation, but new tissue does not fill the cartilage defect	Depending on the location and size of the lesion and the structural integrity, stability, and alignment of the joint, the lesion may or may not progress to cartilage degeneration
Cartilage and bone disruption (osteochondral fractures)	May cause mechanical symptoms, synovitis, pain, and joint effusions	Formation of a fibrin clot, inflammation, invasion of new cells, and production of new chondral and osseous tissue	Depending on the location and size of the lesion and the structural integrity, stability, and alignment of the joint, the lesion may or may not progress

cartilage defect. Platelets within the clot release vasoactive mediators and growth factors or cytokines (small proteins that influence multiple cell functions, including migration, proliferation, differentiation, and matrix synthesis), including transforming growth factor beta and platelet-derived growth factor. Bone matrix also contains growth factors, including transforming growth factor beta, bone morphogenic protein, platelet-derived growth factor, insulinlike growth factor I, insulinlike growth factor II, and possibly others. Release of these growth factors may have an important role in the repair of osteochondral defects. In particular, they probably stimulate vascular invasion and migration of undifferentiated cells into the clot and influence the proliferative and synthetic activities of the cells. Shortly after entering the tissue defect, the undifferentiated mesenchymal cells proliferate and synthesize a new matrix. Within two weeks of injury, some mesenchymal cells assume the rounded form of chondrocytes and begin to synthesize a matrix that contains type II collagen and a relatively high concentration of proteoglycans. These cells produce regions

of hyalinelike cartilage in the chondral and bone portions of the defect. Six to eight weeks following injury, the repair tissue within the chondral region of osteochondral defects contains many chondrocytelike cells in a matrix consisting of type II collagen, proteoglycans, some type I collagen, and noncollagenous proteins. Unlike the cells in the chondral portion of the defect, the cells in the bony portion of the defect produce immature bone, fibrous tissue, and hyalinelike cartilage.

The chondral repair tissue typically has a composition and structure intermediate between that of hyaline cartilage and fibrocartilage; and it rarely, if ever, replicates the elaborate structure of normal articular cartilage (Buckwalter *et al.*, 1988a, 1988b; Buckwalter and Mankin, 1997a, 1997b). Occasionally, the cartilage repair tissue persists unchanged or progressively remodels to form a functional joint surface. But in most large osteochondral injuries, the chondral repair tissue begins to show evidence of depletion of matrix proteoglycans, fragmentation and fibrillation, increasing collagen content, and loss of cells with the appearance of

chondrocytes within a year or less. The remaining cells often assume the appearance of fibroblasts as the surrounding matrix comes to consist primarily of densely packed collagen fibrils. This fibrous tissue usually fragments and often disintegrates, leaving areas of exposed bone. The inferior mechanical properties of chondral repair tissue may be responsible for its frequent deterioration (Buckwalter and Mow, 1992; Buckwalter and Mankin, 1997). Even repair tissue that successfully fills osteochondral defects is less stiff and more permeable than normal articular cartilage, and the orientation and organization of the collagen fibrils in even the most hyalinelike cartilage repair tissue does not follow the pattern seen in normal articular cartilage. In addition, the repair tissue cells may fail to establish the normal relationships between matrix macromolecules, in particular, the relationship between cartilage proteoglycans and the collagen fibril network. The decreased stiffness and increased permeability of repair cartilage matrix may increase loading of the macromolecular framework during joint use, resulting in progressive structural damage to the matrix collagen and proteoglycans, thereby exposing the repair chondrocytes to excessive loads and further compromising their ability to restore the matrix.

Clinical experience and experimental studies suggest that the success of chondral repair in osteochondral injuries may depend to some extent on the severity of the injury, as measured by the volume of tissue or surface area of cartilage injured and the age of the individual (Buckwalter *et al.*, 1996). Smaller osteochondral defects that do not alter joint function heal more predictably than larger defects that may change the loading of the articular surface. Potential age-related differences in healing of chondral and osteochondral injuries have not been thoroughly investigated, but bone heals more rapidly in children than in adults, and the articular cartilage chondrocytes in skeletally immature animals show a better proliferative response to injury and synthesize larger proteoglycan molecules than those from mature animals (Buckwalter *et al.*, 1993, 1994b; Martin and Buckwalter, 1996a, 1996b, 2000; Martin *et al.*, 1997). Furthermore, a growing synovial joint has the potential to remodel the articular surface to decrease the mechanical abnormalities created by a chondral or osteochondral defect.

## V. PREVENTING JOINT DEGENERATION FOLLOWING INJURY

Orthopedic surgeons routinely perform extensive surgical procedures, some having substantial complication rates, in an effort to restore the alignment and congruity of articular surfaces following intraarticular fractures (Marsh *et al.*, 2002). The purpose of these procedures is to decrease residual joint incongruity and thereby to decrease focal elevations of contact stress, presumed to be responsible for posttraumatic osteoarthritis. These widely accepted prac-

tices are based largely on the assumption that joints are less likely to develop osteoarthritis if the peak stresses on focal areas of the articular surface are reduced. However, there is little evidence to guide surgeons in determining how much stress the articular surface can tolerate, in the form of either acute impact or chronically increased stress, and the potential for human joints to repair and remodel the articular surface after injury is poorly understood.

With better understanding of the role of mechanical forces in the pathogenesis of osteoarthritis, clinical and basic research could be focused on developing new, minimally invasive, and nonsurgical treatments of joint injuries that have a high risk of posttraumatic osteoarthritis and on treatments that prevent or delay the development of joint degeneration in patients at high risk of posttraumatic osteoarthritis. There is increasing evidence that biologic interventions can decrease mechanical stress-induced chondrocyte damage. For example, the work of D'Lima and coworkers (2001a, 2001b, 2001c) shows that caspase inhibition can decrease mechanically induced chondrocyte and apoptosis, and Haut and colleagues have reported that P188 surfactant can limit chondrocyte necrosis following impact loading (Phillips and Haut, 2004; Rundell *et al.*, 2005). Other investigations show that antioxidants can prevent mechanically induced chondrocyte damage (Kurz *et al.*, 2004; Beecher *et al.*, 2006).

## VI. PROMOTING ARTICULAR SURFACE REPAIR

Better understanding of articular-cartilage injuries and recognition of the limitations of the natural repair responses have contributed to the recent interest in cartilage repair and regeneration (Buckwalter *et al.*, 1990; Buckwalter, 1992; Buckwalter and Mow, 1992; Buckwalter and Lohmander, 1994; Buckwalter and Martin, 1995; Buckwalter, 2004). In the last three decades clinical and basic scientific investigations have shown that implantation of artificial matrices, growth factors, perichondrium, periosteum, and transplanted chondrocytes and mesenchymal stem cells can stimulate formation of cartilaginous tissue in synovial joint osteochondral and chondral defects (Buckwalter and Lohmander, 1994; Buckwalter *et al.*, 1994a; Buckwalter, 1996a, 1996b, 2004; Messner and Gillquist, 1996; Buckwalter and Mankin, 1997).

### Penetration of Subchondral Bone

Experimental and clinical investigations show that penetration of subchondral bone leads to formation of fibrocartilagenous repair tissue on the articular surfaces of synovial joints (Buckwalter and Lohmander, 1994; Buckwalter *et al.*, 1996; L. L. Johnson, 1996; Mithoefer *et al.*, 2005; Gudas *et al.*, 2006). In regions with full-thickness loss or advanced degeneration of articular cartilage, penetration of the exposed subchondral bone disrupts subchondral blood vessels,

leading to formation of a fibrin clot that fills the bone defect and usually covers the exposed bone surface (Buckwalter and Lohmander, 1994; Buckwalter *et al.*, 1996). If the surface is protected from excessive loading, undifferentiated mesenchymal cells migrate into the clot, proliferate, and differentiate into cells with the morphologic features of chondrocytes (Shapiro *et al.*, 1993). In most instances, over a period of six to eight weeks they form bone in the osseous portion of the defect and fibrocartilaginous tissue in the chondral portion (L. L. Johnson, 1986, 1990; Buckwalter *et al.*, 1990). Initially, the chondral repair tissue can closely resemble articular cartilage in gross and light-microscopic appearance, but it fails to duplicate fully the composition (especially the types and concentrations of collagens and proteoglycans), structure, and mechanical properties of normal articular cartilage, and in many instances it deteriorates with time (Buckwalter *et al.*, 1988, 1990; Buckwalter and Mow, 1992; Buckwalter and Mankin, 1997).

Surgeons currently use a variety of methods of penetrating subchondral bone to stimulate formation of a new cartilaginous surface, including arthroscopic drilling and abrasion of the articular surface and making multiple small-diameter defects or fractures with an awl or similar instrument, a method referred to as the *microfracture technique* (L. L. Johnson, 1986, 1990, 1996; Buckwalter and Lohmander, 1994; Levy *et al.*, 1996; Steadman *et al.*, 1997; Mithoefer *et al.*, 2005a). Multiple authors report that these procedures can decrease the symptoms due to isolated articular-cartilage defects of the knee in a majority of patients (Sprague, 1981; Friedman *et al.*, 1984; L. L. Johnson, 1986, 1990; Ewing, 1990; Levy *et al.*, 1996; Steadman *et al.*, 1997; Mithoefer *et al.*, 2005a).

### Periosteal and Perichondrial Grafts

The potential benefits of periosteal and perichondrial grafts include introduction of a new cell population along with an organic matrix and some protection of the graft or host cells from excessive loading. Animal experiments and clinical experience show that perichondrial and periosteal grafts placed in articular-cartilage defects can produce new cartilage (Salter, 1993; Buckwalter and Lohmander, 1994). O'Driscoll has described the use of periosteal grafts for the treatment of isolated chondral and osteochondral defects and demonstrated that these grafts can produce a new articular surface (O'Driscoll and Salter, 1986; O'Driscoll *et al.*, 1988; Buckwalter, 1996). Other investigators have reported encouraging results with perichondrial grafts (Engkvist and Johansson, 1980; Homminga *et al.*, 1990). However, one study suggests that increasing patient age adversely affects the results of soft-tissue grafts. Seradge *et al.* (1984) studied the results of rib perichondrial arthroplasties in 16 metacarpophalangeal joints and 20 proximal interphalangeal joints at a minimum of three years following surgery. Patient age was directly related to the results. One hundred percent of the patients in their twenties and 75% of the patients in their

thirties had good results following metacarpophalangeal-joint arthroplasties. Seventy-five percent of the patients in their teens and 66% of the patients in their twenties had good results following proximal interphalangeal-joint arthroplasties. None of the patients older than 40 years had a good result with either type of arthroplasty. The clinical observation that perichondrial grafts produced the best results in younger patients (Seradge *et al.*, 1984) agrees with the concept that age may adversely affect the ability of undifferentiated cells or chondrocytes to form an articular surface or that with age the population of cells that can form an articular surface declines (Buckwalter *et al.*, 1993; Martin *et al.*, 1997; Martin and Buckwalter, 2000).

### Cell Transplantation

Transplantation of cells grown in culture provides another method of introducing a new cell population into chondral and osteochondral defects. Experimental work has shown that both chondrocytes and undifferentiated mesenchymal cells placed in articular-cartilage defects survive and produce a new cartilage matrix (Wakitani *et al.*, 1988, 1989, 1994a, 1994b, 1994c; Buckwalter and Mankin, 1997). In addition to these animal experiments, orthopedic surgeons have used autologous chondrocyte transplants for treatment of localized cartilage defects (Brittberg *et al.*, 1994, 1996; Peterson, 1996; Minas and Peterson, 1997; Fu *et al.*, 2005; Mithoefer *et al.*, 2005b). Proponents of this procedure report that it produces satisfactory results, including the ability to return to demanding physical activities, in as many as 90% of patients (Minas and Peterson, 1997; Mithoefer *et al.*, 2005b).

### Artificial Matrices

Treatment of chondral defects with growth factors or cell transplants requires a method of delivering and in most instances at least temporarily stabilizing the growth factors or cells in the defect. For these reasons, the success of these approaches often depends on an artificial matrix. In addition, artificial matrices may allow, and in some instances stimulate, ingrowth of host cells, matrix formation, and binding of new cells and matrix to host tissue (Paletta *et al.*, 1992; Hoemann *et al.*, 2005). Investigators have found that implants formed from a variety of biologic and nonbiologic materials, including treated cartilage and bone matrices, collagens, hyaluronan, chitosan, fibrin, carbon fiber, hydroxylapatite, porous polylactic acid, polytetrafluoroethylene, polyester, and other synthetic polymers, facilitate restoration of an articular surface (Buckwalter and Lohmander, 1994; Buckwalter and Mankin, 1997; Dorotka *et al.*, 2005; Hoemann *et al.*, 2005; Nehrer *et al.*, 2006). Lack of studies that directly compare different types of artificial matrices makes it difficult to evaluate their relative merits, but the available reports show that this approach may contribute to restoration of an articular surface.

## Growth Factors

Growth factors influence a variety of cell activities, including proliferation, migration, matrix synthesis, and differentiation. Many of these factors, including the fibroblast growth factors, insulinlike growth factors, and transforming growth factor betas, have been shown to affect chondrocyte metabolism and chondrogenesis (Buckwalter and Lohmander, 1994; Buckwalter *et al.*, 1996; Henson *et al.*, 2005; Schmidt *et al.*, 2006). Bone matrix contains a variety of these molecules, including transforming growth factor betas, insulinlike growth factors, bone morphogenic proteins, platelet-derived growth factors, and others (Buckwalter *et al.*, 1995, 1996). In addition, mesenchymal cells, endothelial cells, and platelets produce many of these factors. Thus, osteochondral injuries and exposure of bone due to loss of articular cartilage may release these agents, which affect the formation of cartilage repair tissue, and they probably have an important role in the formation of new articular surfaces after currently used surgical procedures, including penetration of subchondral bone. Local treatment of chondral or osteochondral defects with growth factors has the potential to stimulate restoration of an articular surface (Hunziker and Rosenberg, 1994, 1996; Hunziker, 2001; Schmidt *et al.*, 2006). Despite the promise of this approach, the wide variety of growth factors, their multiple effects, the interactions among them, and the possibility that the responsiveness of cells to growth factors may decline with age (Buckwalter *et al.*, 1993; Pfeilschifter *et al.*, 1993; Martin and Buckwalter, 1996; Martin *et al.*, 1997) have made it difficult to develop a simple strategy for using these agents to treat articular-surface injuries. However, development of growth factor-based treatments for isolated chondral and osteochondral injuries in combination with other approaches, including use of artificial matrices and cell

transplants, appears promising (Buckwalter, 2004; Fan *et al.*, 2006).

## VII. CONCLUSION

Articular-surface injuries are a significant unsolved problem. They are common, the value of current treatments is uncertain, and many of these injuries initiate progressive joint degeneration, a condition recognized as posttraumatic osteoarthritis. Surgeons attempt to decrease the risk of posttraumatic osteoarthritis by restoring joint stability, congruity, and alignment following injury. In addition, to promote repair and remodeling of damaged articular surfaces, they penetrate subchondral bone and insert periosteal and perichondral grafts and autologous chondrocytes. The results of these procedures vary considerably among patients, and there is limited information concerning the long-term outcomes. However, the available studies of people who have suffered joint injuries indicate that even with optimal current treatment the risk of posttraumatic osteoarthritis is high following chondral tears and articular-surface fractures. For this reason there is a clear need to improve the treatment of joint injuries. Clinical and experimental studies show that chondrocyte and mesenchymal stem cell transplantation, synthetic matrices, growth factors, and combinations of these treatments have the potential to restore articular surfaces. Other investigations suggest that biologic interventions may minimize chondrocyte damage due to mechanical forces. The most dramatic improvements in the treatment of articular-surface injuries are likely to come from approaches that help maintain chondrocyte viability and function, restore joint stability and congruity, and promote articular-surface repair and remodeling following joint injury.

### I. INTRODUCTION

Ligament bioengineering involves some particular technological challenges. Synthetic, semisynthetic, or natural scaffolds are under development to establish optimal conditions for permanent replacement of torn ligaments. The anterior cruciate ligament (ACL) of the knee joint, one of the strongest ligaments of the body, is often the target of traumatic injuries. Unfortunately, its healing potential is limited, and the surgical options for its replacement are frequently associated with knee instability, pain, or muscular weaknesses. Several parameters must be taken into account to produce a graftable bioengineered ACL (bACL) for the permanent replacement of a torn ACL. First, biocompatibility of the bACL will determine its level of integration in the bone knee joint. Second, the ultrastructure of its scaffold is critical for cell colonization, before and/or after implantation. Third, the biomechanical features of the bACL must be adequate to sustain the physiological stress that will be applied on its structure postgrafting. Finally, the regeneration and remodeling of the bACL is expected to occur *in situ* postimplantation, leading to a functional ACL that plays its role as a knee joint stabilizer. Our research group has developed a bACL that seems to possess these various advantages and may eventually be used for torn-ACL replacement in humans. Our tissue-engineering approach and concepts are presented in this chapter.

The need for human tissues and organs has increased over the last few years, mostly because of population growth.

The risks for transmission of contagious diseases have also imposed serious restrictions on the availability of human transplants. Recent advances in tissue and organ engineering have generated a lot of interest among clinicians and patients in various fields of medicine. Tissue engineering offers the opportunity to target and control various biophysiological parameters of tissue development to make it competent for implantation; for example, collagen fibers and cells can be aligned in culture under defined conditions (Black *et al.*, 1999; Huang *et al.*, 1993; Kanda and Matsuda 1994; Kim *et al.*, 1999; Goulet *et al.*, 2000; Paquette *et al.*, 2003). Perhaps most importantly, bioengineered tissue substitutes are expected to respond and adapt to the mechanical stresses that occur following implantation *in vivo* (Goulet *et al.*, 2004). This chapter is dedicated to ligament and tendon bioengineering. The technological approach developed to produce a tissue-engineered human anterior cruciate ligament substitute is described. A bioengineered ACL (bACL) was developed by seeding human ligament fibroblasts in a hydrated collagen matrix (Goulet *et al.*, 2000, 2004). This bACL is anchored with two bones, since bone-to-bone insertion is reported as the most secure method for ligament fixation (Amiel *et al.*, 1986; Arnoczky *et al.*, 1982). Such an ACL substitute is a good tool to study connective-tissue repair and the environmental and cellular factors that may affect collagen alignment, cross-linking, and remodeling *in vitro*. It may also become a therapeutic alternative for torn-ACL replacement, considering the promising outcomes

observed *in vivo* postimplantation in the caprine model (Goulet *et al.*, 2004).

## II. NEED FOR BIOENGINEERED TENDON AND LIGAMENT SUBSTITUTES

In the United States alone, at least 120,000 patients per year undergo tendon or ligament repairs (Langer and Vacanti, 1993), including approximately 50% surgical ACL reconstructions requested, using various surgical approaches (Frank and Jackson, 1997). The rupture of an ACL of the knee joint frequently occurs during sports activities such as skiing, snowboarding, soccer, and hockey. Several mechanisms can lead to ACL rupture. An ACL injury may result from a violent twisting of the knee, which can happen when an athlete plants his or her foot and suddenly changes direction. The ACL can also tear if the knee is hyperextended. Almost any sport that involves jumping, cutting, or twisting has an inherent risk of an ACL rupture. The completely torn or disrupted ACL does not appear to heal very well, at least to the extent that healing leads to a return to function (Hart *et al.*, 2005). The therapeutic options for ACL reconstruction include three categories of ACL substitutes: (1) synthetic prostheses, (2) allogenic natural substitutes (ACL excised from cadavers), and (3) natural autografts (central portion of the patellar tendon or hamstring tendon of the patient). Unfortunately, none of these surgical alternatives provides a long-term optimal solution. Synthetic material implantation was a very popular surgical technique in the 1980s, but it frequently led to implant degeneration and failure (Olson *et al.*, 1988; Woods *et al.*, 1991). Joint laxity occurs with synthetic prostheses about 12 months postsurgery. The result of ACL reconstruction with nondegradable prostheses has shown many problems, including long-term failure due to synovitis, arthritis, and mechanical deterioration. Other issues include lack of supportive-tissue ingrowth or disorganized and weak tissue formation. Stress shielding is also a major concern because the host tissue will not remodel or mature if the mechanical load is maintained by the prosthesis. For these reasons, synthetic prostheses are not the first option chosen (Olson *et al.*, 1988; Woods *et al.*, 1991; Cloutier *et al.*, 1993; Frank and Jackson, 1997). However, some new biosynthetic materials are under investigation (Laurencin and Freeman, 2005).

The use of allograft substitutes (ACL taken from cadavers) overcomes the need for autologous tissues, avoiding donor-site morbidity. However, it has limitations, considering the factors of failure, including risks of disease transmission, graft rejection, and inflammation (Noyes *et al.*, 1994; Sterling *et al.*, 1995). Allogeneic grafting of ligaments is still at an experimental stage and may lead to immunologic reactions that prevent good wound healing (Jackson and Kurzweil, 1991; Sabiston *et al.*, 1990). In fact, the main problem associated with this option for ACL replacement is the decellularization of the allografts prior to implantation.

The dead cells present in these tissues must be eliminated to reduce considerably the risks of immune rejection postgrafting. Detergents are used to reach this goal, but they also alter the structure of the scaffold and the quality of the collagen fibers that support the tissues. Moreover, residual traces of detergents such as SDS cannot be totally eliminated from the allografts, hampering repopulation of the implants by host cells *in situ* postgrafting. Finally, cell debris can remain attached to the decellularized scaffold of the allografts and potentially induce inflammatory reactions postgrafting.

Assuming proper processing techniques, autografts using the patellar tendon (Fulkerson and Langeland, 1995; Stengel *et al.*, 2005), quadriceps tendon–patellar bone (Chen *et al.*, 1999), or the hamstring tendons (Puddu and Ippolito, 1983) avoid immune rejection problems. Permanent attachment of ACL prosthesis to bone is of critical importance. Since the mid-1990s, the best solution has been the bone–patellar tendon–bone grafts (Kragh and Branstetter, 2005). Unfortunately, ligament translation or laxity is observed postsurgery (Stengel *et al.*, 2005), adding to the morbidity associated with the partial loss of a healthy tendon, chronic knee pain, loss of motion, knee instability, quadriceps weakness, and patella rupture (Vergis and Gillquist, 1995). Little is known about the physiological and pathological events that regulate the histological organization of ACL *in vivo* (Frank, 2004).

This chapter summarizes the recent advances in the domain of tendon and ligament bioengineering. Tissue engineering has engendered considerable interest, notably for its potential applications in orthopedic surgery, since ligaments and tendons are frequently targets of sports and aging trauma.

## III. HISTOLOGICAL DESCRIPTION OF TENDONS AND LIGAMENTS

Tendons connect bones and muscles, while ligaments join one bone to another. The literature used to describe the histological structures of fascia, tendons, and ligaments as similar. They are dense connective tissues consisting of fibroblasts surrounded by type I collagen bundles (Amiel *et al.*, 1984). This may explain why patellar tendon and tensor fascia have frequently been used to replace the torn anterior cruciate ligament of the knee joint (Arnoczky *et al.*, 1982). The central quadriceps tendon autograft was reported as a promising alternative for ACL reconstruction (Fulkerson and Langeland, 1995). However, some pain, loss of motion, knee instability, and other problems can be associated with this approach (Tanzer and Lenczner, 1990; Tria *et al.*, 1994; Vergis and Gillquist, 1995), according to the type of trauma and depending on variables unique to each individual (Harner *et al.*, 1994; Johnson *et al.*, 1992; Parker *et al.*, 1994). The success of such grafts depends on the revascularization of the transplanted tissues progressively surrounded by a

synovial membrane, rich in vessels (Arnoczky *et al.*, 1982). The tendon would finally gain some ligament properties, and the word *ligamentization* was applied by Amiel *et al.* (1986), to describe this physiological phenomenon studied *in vivo* postgrafting.

Both ligaments and tendons consist mainly of closely packed and thick collagen fibers (predominantly type I, with a small proportion of type III collagen) but also include small quantities of glycosaminoglycans (dermatan sulfate and hyaluronic acid) (Danylchuk *et al.*, 1978; Watanebe *et al.*, 1994). The composition of these biochemical constituents is modulated during tissue growth and development, also changing in response to functional requirements (Watanebe *et al.*, 1994).

Tendon collagen fibrillogenesis is initiated early in development by fibroblasts (Trelstad and Hayashi, 1979). Fibrils are embedded in an organized, hydrated proteoglycan matrix and cross-linked through aldol or Schiff base adducts between aldehydes on one or more of the  $\alpha$ -chains of the collagen molecules and aldehydes or amino groups on adjacent chains or molecules (Davison, 1989). Such cross-links contribute to the tensile strength of the fibrils and, thus, to the tensile properties of the whole tendon (Davison, 1989). The aldehyde-derived cross-links are found in two forms: Some are unstable in dilute acids and others are stable (Davison, 1989). The ratio of one form to the other varies in different tissues, generally increasing with aging.

Data reported by Amiel *et al.* (1984) suggested that ligaments are more metabolically active than tendons, having plumper cellular nuclei, higher DNA content, larger amounts of reducible cross-links, and more type III collagen, as compared with tendons. They also contain slightly less total collagen than tendons and more glycosaminoglycans, particularly close to the joint (Amiel *et al.*, 1984).

Extracellular matrix fibers in ligaments are also arranged less regularly than in tendons (Puddu and Ippolito, 1983), although the fibers are oriented parallel to the longitudinal axis of both tissues (Amiel *et al.*, 1984). For example, the ACL is composed of multiple fascicles, the basic unit of which is type I collagen (Bessette and Hunter, 1990). The collagen fibrils are nonparallel but are themselves arranged into fibers oriented roughly along the long axis of the ligament in a wavy, undulating pattern ("crimp"), which slowly straightens out as small loads are applied to the ligament (Bessette and Hunter, 1990). To give an example of the forces applied on such tissues *in vivo*, the ACL usually supports loads of about 169 newtons and ruptures around 1730 newtons (Bessette and Hunter, 1990). An elongation of only 6% (about 2 mm) of human ACL (about 32 mm long) is reported to be the limit beyond which damage must be expected (Amis and Dawkins, 1991). Thus, the main challenge associated with the production of bioengineered tendons and ligaments is to obtain strong and functional tissues.

## IV. TISSUE-ENGINEERED ACL SUBSTITUTES

### Basic Features of Bioengineered ACLs

Several approaches are proposed to produce bioengineered tissues *in vitro*. However, the development of such a technology always involves the use of biocompatible and, preferably, biodegradable materials that (1) can provide mechanical resistance and (2) can be colonized and reorganized by living cells *in situ* postgrafting. Indeed, some tendons and ligaments are at the top of the list in terms of injury frequency and problems to repair, replace, or heal. As often reported, in contrast with the medial collateral ligament, ACL regeneration is hampered *in vivo* (Lyon *et al.*, 1991; Ross *et al.*, 1990). Moreover, certain anatomic factors may predispose people to ACL injury (Harner *et al.*, 1994). In the young and active population, reconstruction is often the best therapeutic option. However, to overcome the drawbacks associated with ACL repair and healing, several efforts have been made to produce a bioengineered ACL model over the last decade (Petrigliano *et al.*, 2006; Spindler *et al.*, 2006). Selecting the right scaffold for the starting point to build a bACL is going to impact the outcome (Petrigliano *et al.*, 2006).

In a composite material, the orientation and density of fibers in the matrix significantly affect its mechanical properties. From a macroscopic point of view, the ACL can also be considered a composite material, where the fibroblasts secrete collagen that undergoes fibrillogenesis. Hence, it is not surprising to see that human ligaments have a very low stiffness in traction for small strains, because of the cross-linked organization of the fibers (Strocchi *et al.*, 1992).

Collagen remains the basic protein of interest in the field of connective-tissue bioengineering. Dunn *et al.* (1992, 1993, 1994) reported successful replacement of ACL by cross-linked collagen prostheses implanted in rabbits. A similar approach was also reported for the regeneration of the Achilles tendon (Kato *et al.*, 1991). The use of native collagen for the production of tissue-engineered ligaments leads to a better understanding of the mechanisms responsible for its secretion by the cells, its assembly, and its remodelling. Thus, collagen alone or with cells isolated from the tissue of origin was used to produce bioengineered functional tissues *in vitro*. The main idea behind such attempts was first to produce *in vitro* models of ligaments or tendons by tissue engineering in order to implant them permanently *in vivo*, where their histological and functional properties should be improved by local and systemic stimuli.

### A New Living bACL

A new concept for the production of human bACL *in vitro* was developed in our laboratory. This approach combines the skills and knowledge associated with tissue culture

and biomechanical principles. Such expertise has been successfully developed in our laboratory for other bioengineered tissues, such as human skin (Auger *et al.*, 1995; Black *et al.*, 1999), human bronchi (Goulet *et al.*, 1996; Paquette *et al.*, 2003, 2004), and human blood vessels (L'heureux *et al.*, 2001). Our research programs aim at producing bioengineered tissues that could serve both experimental and clinical interests.

The main differences between our bACL and other ligament models are the following advantages: (1) It contains living ACL fibroblasts that contract, synthesize, and initiate remodeling and organization of the extracellular matrix in which they are initially seeded in culture; (2) it could be a very useful tool to study connective tissue repair *in vitro*, since the cells can maintain their activities for at least two months in culture; (3) it is produced without chemical cross-linking agents and synthetic material; (4) it avoids healthy ligament or tendon donor-site morbidity; and (5) bones are used to anchor the bACL, being included in the bACL structure right from the start of its production, to facilitate its eventual transplantation *in vivo*. Such an ACL substitute would greatly reduce the risks of immune reactions and infections and promote the permanent graft integration posttransplantation. This approach also eliminates the risks of chemical cytotoxicity and the production of foreign molecules due to mechanical friction, which could occur *in vivo*, in the case of its eventual use as an ACL substitute (Olson *et al.*, 1988).

### Autologous Cell Seeding of bACLs

We preferentially have used autologous ACL fibroblasts to cellularize the bACLs grafted in goat knee joints. However, other sources of autologous fibroblasts, and possibly mesenchymal stem cells, could be seeded in bACLs *in vitro*, to assess their capacity to contract, synthesize, and remodel the collagen fiber network that composes the tissue scaffold. Animal experimentation could also be initiated to evaluate the histological and biomechanical properties of bACLs seeded with ACL fibroblasts as compared to grafts populated with other sources of cells. The phenotypic stability of stem cell-derived fibroblasts would have to be monitored during several passages in culture before considering cellularization of bACLs with these cells. Stem cell-derived fibroblasts, expected to show faster doubling times and a longer life span than ACL cells *in vitro*, may differentiate into various cellular phenotypes in response to the physiological environment and the biomechanical stimuli that characterize functional knee joints. Therefore, until animal experimentation is performed, it would be premature to use stem cells to populate bACLs.

### Matrix Remodeling in Response to Mechanical Stimuli

Various research groups have shown that fibroblasts seeded in collagen gels can degrade and reorganize the sur-

**FIG. 60.1.** bACL native collagen scaffold. Photomicrograph taken during scanning electron microscope analyses of an acellular bACL bovine type I collagen scaffold that shows the alignment of the fibers in response to static tension applied for 24 h on the tissue in culture ( $\times 6000$ ).

rounding extracellular matrix and adopt a specific orientation in a contracted collagen lattice as a function of culture conditions and time (Auger *et al.*, 1995; López Valle *et al.*, 1992b; Bell *et al.*, 1981; Delvoye *et al.*, 1983; Grinnell and Lamke, 1984; Guidry and Grinnell, 1985, 1986; Kasugai *et al.*, 1990). Several studies have also shown that mechanical stimuli to biological tissues can produce ultrastructural and histological content variations. For instance, it is well known that ligament remodeling depends on the mechanical stress to which it is subjected *in vivo* (Amiel *et al.*, 1984). In addition, bACL so far produced have collagen and cells aligned in a parallel direction to the stress exerted (Goulet *et al.*, 2000, 2004). Finally, Huang *et al.* (1993) previously reported that the mechanical properties along with the ultrastructure of ligament equivalents change in response to mechanical strengthening *in vitro*. Similar observations were made following *in vitro* elongation studies on rabbit ACL (Matyas *et al.*, 1994). Thus, it is possible and structurally relevant to induce the parallel alignment of the matrix fibers that compose the scaffold of a tissue-engineered ACL substitute in culture (Fig. 60.1). This alignment can be achieved by subjecting the bACL to static or dynamic longitudinal stretching *in vitro* (Goulet *et al.*, 2000) (Fig. 60.2). We previously reported that fibroblasts isolated from human ACL biopsies and seeded in a collagen matrix can secrete and reorganize matricial fibers in response to static tension (Goulet *et al.*, 1997a, 1997b).

### Strength of the bACL at the Time of Implantation

*In vitro*, the strength of the bACL does not compare with the strength of native ACL. Therefore, when a bACL is

**FIG. 60.2.** A bACL maintained under tension *in vitro*. Macroscopic view of an acellular bACL subjected to minimal static tension for 24 h in culture.

produced for knee joint implantation, a polyglyconate MAXON surgical thread (size 3–0), resorbable within six weeks postgrafting, can be used initially to reinforce tissue structure. The thread is passed through holes made in the two bone plugs anchoring the bACL and is then tied (Goulet *et al.*, 2004). The bone plugs and thread are counterrotated to provide a stronger link between the osseous anchors. For casting the bACLs, DMEM containing fetal calf serum (FCS) and 1.0 mg/mL of solubilized bovine type I collagen is quickly mixed with a suspension of autologous ACL fibroblasts ( $2.5 \times 10^5$  cells/mL). The mixture is poured into tubes containing the bone plugs linked by the surgical thread. These bACLs are cultured for 24 h in DMEM supplemented with 10% FCS, 50  $\mu$ g/mL ascorbic acid, and antibiotics, during which time the collagen is contracted by the cells onto and around the twisted surgical thread. The bACLs are frozen overnight at  $-70^\circ\text{C}$  and subsequently lyophilized (Fig. 60.3A). In culture, in the absence of a lyophilized core and of the resorbable thread, all bACL matrix would break at the bone–collagen interface at forces varying from 0.2 to 0.5 N. When a lyophilized core is added, the bACL can support up to 2 N before rupture. This step aims at gathering the collagen fibers that are aligned in the tissue, to reinforce the resulting scaffold. In addition, the biodegradable thread, integrated between the bone plugs that anchor the lyophilized core, allows the bACL to sustain up to 25 N before rupture. Following rehydration of the lyophilized central core in fresh DMEM, a second coating of collagen and cells is applied as described earlier (Fig. 60.3B). A bilayered bACL is obtained with a rehydrated central core and a living, cell-populated outer layer. The bACLs are viable prior to implantation, since the fibroblasts progressively contract the outer collagen layer *in vitro*. The resultant bACLs are kept in culture for about a week until grafted into their respective hosts. After a year *in situ* postgrafting in a goat knee joint, the bACL shows macro-

**FIG. 60.3.** Construction of bACL and postgrafting view *in situ*. (A) Macroscopic appearance of the initial collagen layer contracted onto two bone plugs and lyophilized. scopic features comparable to the contralateral native ACL (Fig. 60.3C).

#### Integration of the bACL in the Goat Knee Joint

Data reported from animal experimentation showed that vascularization, cell migration, tissue remodeling, and extracellular matrix deposition occurred *in vivo* in acellular bACLs 12 weeks postgrafting in the rabbit knee joint (Dunn *et al.*, 1992, 1993, 1994) and in cellularized bACLs a year posttransplantation in the goat knee joint (Goulet *et al.*, 2004). Several research groups are currently involved in the

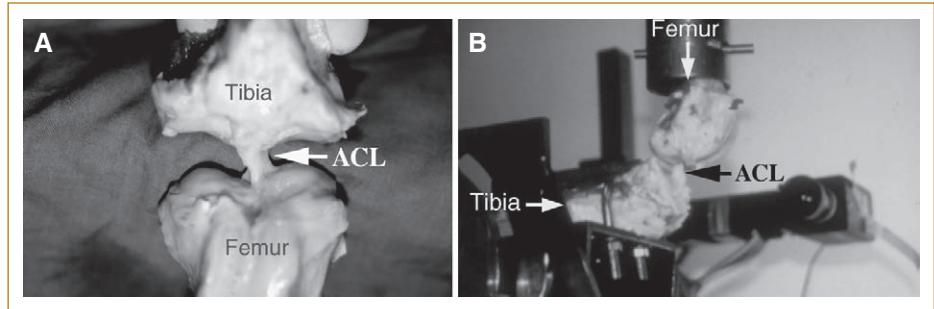

**FIG. 60.4.** Histological analyses *ex vivo* of a bACL, compared to a natural ACL. Light-microscope histology of paraffin sections of bACL grafted in goat knee and stained with Masson's trichrome method showed a dense network of collagen fibers organized in a typical crimp pattern in bACL grafted for 13 months (A) and native ACL (B) ( $\times 120$ ). Vascularization observed in synovial membranes attached to bACLs grafted for one month (C), six months (D), and 11 months (E), compared with blood vessel in contralateral native ACL (F). Light-microscope histology of tissue sections embedded in LR white and stained with toluidine blue showed fibrocartilage and chondrocytes at the junction of the ligament proper and the bone in both the bACL grafted for six months (G) and native ACL (H) ( $\times 150$ ).

development of human bACLs that would include living cells, to obtain tissues sharing several histological and functional properties with natural ACL (Laurencin and Freeman, 2005; Petrigliano *et al.*, 2006). When a bACL is implanted in a goat knee joint, it is slowly populated with host cells. These cells are distributed in the matrix fiber network of the graft and regenerate its collagen matrix (Fig. 60.4A). After a year, the implanted bACL shares several histological properties with a natural ACL (Fig. 60.4B). The presence of structure blood vessels is shown in the bACLs grafted for a month in the caprine model (Fig. 60.4C–E). Similarly, fibrocartilage containing chondrocytes is formed at the bone–ligament interface, contributing to the strengthening of the graft at its insertion sites (Fig. 60.4F). At the insertion sites of both bACL and natural ACL, fibrocartilaginous tissue is apparent,

as evidenced by the cartilage markers aggrecan and link protein, six months after grafting the bACLs (Goulet *et al.*, 2004). Since the bACL does not initially contain any chondrocyte, these data strongly suggest that the ultrastructure of the bovine type I collagen scaffold of the graft allows its colonization and regeneration by host cells *in situ*.

The organization and number of blood vessels in the graft are highly comparable to their distribution in natural ACLs (Fig. 60.4G). The vascularization of the bACL *in situ* postimplantation is certainly the first critical step for its permanent integration in a knee joint. The scaffold of the bACL allows endothelial cells to migrate and form such blood vessels. This phenomenon is dependent on the level of integration of the bone plugs of the bACL into the bones of the host knee joint. The vascularized graft being exposed to

**FIG. 60.5.** Rupture assay of a bACL *ex vivo*. Macroscopic view of an 11-month-old graft *ex vivo* as prepared for biomechanical testing before (A) and during (B) application of tension prior to rupture.

nutriments, its matrix remodeling and strengthening can be initiated. Thus, the bACL seems to offer a promising alternative for torn-ACL replacement in a knee joint.

### Matrix Remodeling and Biomechanical Reinforcement of the bACL *In Vivo*

During the animal implantation phase, the reinforcement of the grafted bACL progresses slowly in response to the mechanical stimuli that occur in the host knee joint (Goulet *et al.*, 2004). The ultimate strength of each graft *ex vivo* is evaluated using an Instron traction machine (Fig. 60.5). The average bACL strength from seven grafted knees was 23% after 11 months and 36% after 13 months, compared with the average ultimate strengths of natural goat ACL corresponding to 100% (Goulet *et al.*, 2004). This strengthening can be compared to the evolution of the bone–patellar ligament–bone autograft currently used for ACL reconstruction in human knees. This type of autograft weakens *in situ* at about six weeks posttransplantation. Despite this decrease in functionality, when such a graft is successful, it is slowly revascularized after about six weeks. It gains most ACL histologic and functional properties after 30 weeks in humans. Such a physiological process was first called *ligamentization* by Amiel *et al.* (1986). Observations made in the goat knee joint suggest that a similar tissue remodeling occurs *in vivo* in tissue-engineered ACLs (Goulet *et al.*, 2004). Such remodeling is expected progressively to bring the bACL mechanical properties to an optimal level in the knee joint.

## V. CONCLUSION

Recent advances in bioengineering and cellular biology have led to revolutionary new therapeutical applications in many medical fields. The bioengineered ligament model described in this chapter presents features that can be modulated throughout culture conditions and time *in vitro* (our bACL) and very likely *in vivo* postgrafting in animals.

One of the major problems in the implantation of bACL is the fixation of the graft to the bone. Presently, one of the most popular options for reconstruction is using the patellar tendon (Arnoczky *et al.*, 1982) with a piece of spongy bone at each end. In the bACL we have developed *in vitro*, the spongy bone structure allows the penetration of the

collagen matrix among its trabeculae prior to its polymerization. This approach for bioengineered ligament fixation seems promising, since it facilitates surgical manipulations and promotes graft integration in the knee joint of the host. Synthetic bone plugs will be interesting alternatives to assess prior to clinical applications of the bACL as a torn-ACL substitute.

Nevertheless, the main advantages of our bACL over other ligament models stem from its histological organization, which is progressively modulated by the living ACL fibroblasts included in its structure *in vitro*. Because fibroblasts seeded in the bACL secrete and reorganize extracellular matrix constituents in culture, it makes it a promising tool to study the role of various cellular elements involved in the maintenance or induction of ligament repair *in vitro*.

This chapter was meant to give the reader an overview of the recent achievements and approaches that combine cell biology and tissue-engineering concepts to produce tendons and ligaments in culture. These bioengineered tissues will indeed have to be optimized prior to human transplantation. However, investigators involved in this domain have not yet started to exploit all the possibilities offered by such a new biotechnological concept. For instance, gene therapy might find some interesting applications by introducing living transfected cells within various types of bioengineered tissues.

Despite the fact that challenges lie ahead for those aiming at reproducing tissues and organs *in vitro*, we can all be hopeful, looking at the ongoing advances reached in various medical fields through tissue bioengineering (Langer and Vacanti, 1993). It is quite probable that in the near future, people will benefit from bioengineered tendon and ligament substitutes. Their production would start in a laboratory and reach its final completion in a human body. It is well recognized that a delay of six weeks after injury is required before ACL surgery is performed. In fact, it is better to perform surgical intervention of the ACL when the nearly normal range of motion of the knee has returned and inflammation has been mostly eliminated (Johnson *et al.*, 1992). This delay could be long enough to allow the production of a bACL *in vitro*. Engineering of autologous ACL would avoid the need for detrimental harvesting of the patient's tissues,

like a sample of the patellar tendon. This approach may limit the needs for knee surgery, since it may be possible to graft a bACL anchored with bones simply by arthroscopy. In addition, bioengineered tissues cannot be rejected post-grafting when produced with autologous cells. That is the

joint ultimate goal shared by researchers and clinicians in the various research teams around the world. Such a realization would certainly revolutionize the present therapeutic skills in tendon and ligament implantation.

## VI. ACKNOWLEDGMENTS

Dr. Albert Normand died early after the initiation of our work on human-ligament bioengineering. Our research team wants to express our sincere gratitude to this devoted orthopedic surgeon, who was the first to propose the concept of bACL development *in vitro*. The authors are also grateful to Drs. Jean Lamontagne and Réjean Cloutier for their contribution as orthopedic surgeons on the implantation of bACLs in the caprine model, to Richard Janvier for sample

preparation for electron microscopy analyses, and to Julie Tremblay and Lina Robayo for technical assistance. This work was supported by the Medical Research Council of Canada, the Canadian Arthritis Society, the Canadian Orthopedic Association, the Foundation of the Enfant-Jesus and Saint-Sacrement Hospitals, and The Club Richelieu de Limoilou, Quebec.

### I. INTRODUCTION

The mechanosensory mechanisms in bone include (1) the cell system that is stimulated by external mechanical loading applied to the bone; (2) the system that transduces that mechanical loading to a communicable signal; and (3) the systems that transmit that signal to the effector cells for the maintenance of bone homeostasis and for strain adaptation of the bone structure. The effector cells are the osteoblasts and the osteoclasts. These systems and the mechanisms they employ have not yet been unambiguously identified. We review here candidate systems. In particular we summarize the current theoretical and experimental evidence suggesting that osteocytes are the principal mechanosensory cells of bone, that they are activated by strain amplification from fluid flowing through the osteocyte canaliculi, and that the electrically coupled three-dimensional network of osteocytes and lining cells is a communications system for the control of bone homeostasis and structural strain adaptation. Finally, the effect of mechanical forces on the differentiation of mesenchymal stem cells into bonelike cells is considered.

It has long been known that living adult mammalian bone tissue adapts its material properties and whole bones adapt their shape in response to altered mechanical loading (Frost, 1964; Wolff, 1870, 1892, 1986). Progress is being made in understanding the cellular mechanisms that accomplish

the absorption and deposition of bone tissue. The physiological mechanism by which the mechanical loading applied to bone is sensed by the tissue and the mechanism by which the sensed signal is transmitted to the cells that accomplish the surface deposition, removal, and maintenance have not been identified. The purpose of this chapter is to review some background research on these mechanosensory mechanisms. See Burger *et al.* (1998) for an earlier review of similar literature.

All vital cells are “irritable,” i.e., capable of perturbation by and response to alterations in their external environment. The mechanosensing process(es) of a cell enable it to sense the presence of and respond to extrinsic physical loadings. This property is widespread in uni- and multicellular animals (French, 1992), plants (Goldsmith, 1994; Wildon *et al.*, 1992), and bacteria (Olsson and Hanson, 1995). Tissue sensibility is a property of a connected set of cells, and it is accomplished by the intracellular processes of mechanoreception and mechanotransduction. *Mechanoreception* is the term used to describe the process that transmits the informational content of an extracellular mechanical stimulus to a receptor cell. *Mechanotransduction* is the term used to describe the process that transforms the mechanical stimulus’ content into an intracellular signal. We employ the term *mechanosensory* to mean both mechanoreception and mechanotransduction.

Additional processes of *intercellular* transmission of transduced signals are required at tissue, organ, and organismal structural levels.

## II. THE CONNECTED CELLULAR NETWORK (CCN)

The bone cells that lie on all bony surfaces are osteoblasts, either active or inactive. Inactive osteoblasts are called *bone-lining cells*; they have the potential of becoming active osteoblasts. The bone cells that are buried in the extracellular bone matrix are the osteocytes. Each osteocyte, enclosed within its mineralized lacuna, has many (perhaps as many as 80) cytoplasmic processes. These processes are approximately 15  $\mu\text{m}$  long and are arrayed three-dimensionally in a manner that permits them to interconnect with similar processes of up to as many as 12 neighboring cells. These processes lie within mineralized bone matrix channels called *canaliculi*. The small space between the cell process plasma membrane and the canalicular wall is filled with bone fluid and macromolecular complexes of unknown composition. All bone cells except osteoclasts are extensively interconnected by the cell process of the osteocytes, forming a *connected cellular network* (CCN) (Cowin *et al.*, 1991; Moss, 1991a, 1991b). The interconnectivity of the CCN is graphically illustrated in Fig. 61.1, a scanning electron micrograph showing the replicas of lacunae and canaliculi *in situ* in mandibular bone from a young subject aged 22 years. The inset shows enlarged lacunae, identified by a rectangle.

The touching cell processes of two neighboring bone cells contain gap junctions (Bennett and Goodenough, 1978; Civitelli, 1995; Doty, 1989; D. B. Jones and Bingmann, 1991; S. J. Jones *et al.*, 1993; Schirmacher *et al.*, 1992). A *gap junction* is a channel connecting two cells. The walls of the channel consist of matching rings of proteins piercing the membrane of each cell; when the rings associated with two cells connect with each other, the cell-to-cell junction is formed. This junction allows ions and compounds of low molecular weight (less than 1 kDa) to pass between the two cells without passing into the extracellular space. The proteins making up a gap junction are called *connexins*; in bone, the protein is either connexin 43 or connexin 45, with 43 predominating (the number refers to the size of the proteins, calculated in kilodaltons) (Cheng *et al.*, 2001; Lecanda *et al.*, 1998; Minkoff *et al.*, 1999). A ring of connexins in one cell membrane is generally called a *connexon* or *hemichannel*. Connexin 43-null mice display inhibited ossification and exhibit increased craniofacial abnormalities, while osteoblasts deficient in this protein show a significant decrease in markers of the osteoblastic phenotype, suggesting that connexin 43 plays a pivotal role in normal osteogenesis (Lecanda *et al.*, 2000). In osteocytes, fluid shear stress causes a redistribution of connexin 43 and an opening of the gap junctions, suggesting that these channels may be used to transmit signals in response to mechanical loading (Cheng *et al.*, 2001).

**FIG. 61.1.** Scanning electron micrograph showing the replicas of lacunae and canaliculi *in situ* in mandibular bone from a young subject age 22 years. The inset shows enlarged lacunae, identified by a rectangle. This micrograph illustrates the interconnectivity of the CCN. From Atkinson and Hallsworth (1983) with permission.

Furthermore, in bone, gap junctions connect superficial osteocytes to periosteal and endosteal osteoblasts. All osteoblasts are similarly interconnected laterally on a bony surface; perpendicular to the bony surface, gap junctions connect periosteal osteoblasts with preosteoblastic cells, and these, in turn, are similarly interconnected. Effectively, each CCN is a true syncytium (Duncan and Mislser, 1989; S. J. Jones *et al.*, 1993; Schirmacher *et al.*, 1992). Gap junctions are found where the plasma membranes of a pair of markedly lapping canalicular processes meet (Rodan, 1992). In compact bone, canaliculi cross the cement lines that form the outer boundary of osteons. Thus extensive communication exists between osteons and interstitial regions (Curtis *et al.*, 1985).

Bone cells are electrically active (Bingmann *et al.*, 1988, 1998; Chesnoy-Marchais and Fritsch, 1988; Massass *et al.*, 1990; Rubinacci *et al.*, 1998). In addition to permitting the intercellular transmission of ions and small molecules, gap junctions allow both electrical and fluorescent dye

transmission (Jeansonne *et al.*, 1979; Lecanda *et al.*, 2000; Moreno *et al.*, 1994; Schirmacher *et al.*, 1993; Spray, 1998). Gap junctions are electrical synapses, in contradistinction to interneuronal, chemical synapses; and, significantly, they permit bidirectional signal traffic (e.g., biochemical, ionic, electrical). In a physical sense, the CCN represents the hard wiring (Cowin *et al.*, 1991; Moss, 1991a, 1991b; Nowak, 1992) of bone tissue.

### III. MECHANOSENSATION ON THE CCN

#### Stimuli

The *stimulus* for bone remodeling is defined as that particular aspect of the bone's stress or strain history that is employed by the bone to sense its mechanical load environment and to signal for the deposition, maintenance, or resorption of bone tissue. The bone tissue domain or region over which the stimulus is felt is called the *sensor* domain. When an appropriate stimulus parameter exceeds threshold values, loaded tissues respond by the triad of bone adaptation processes: deposition, resorption, and maintenance. The CCN is the site of intracellular stimulus reception, signal transduction, and intercellular signal transmission. It is thought that stimulus reception occurs in the osteocyte (Cowin *et al.*, 1991) and that the CCN transduces and transmits the signal to the surface lining or osteoblast. The osteoblasts alone regulate bone deposition and maintenance directly and regulate osteoclastic resorption indirectly (T. J. Martin and Ng, 1994). The possible role of the osteoblast as a stimulus receptor has not yet been thoroughly investigated (Owan *et al.*, 1997). Although it is reasonably presumed that initial mechanosensory events occur at the plasma membrane of the osteocytic soma and/or canalicular processes, the initial receptive and subsequent transductive processes are not well understood.

It follows that the true biological stimulus, though much discussed, is not precisely known. A variety of mechanical loading stimuli associated with ambulation (at a frequency of 1–2 Hz) have been considered for bone remodeling. The majority have followed Wolff (1892, 1986) in suggesting that some aspect of the mechanical loading of bone is the stimulus. The mechanical stimuli suggested include strain (Cowin and Hegedus, 1976), stress (Wolff, 1892, 1986), strain energy (Fyhrie and Carter, 1986; Huiskes *et al.*, 1987), strain rate (Fritton *et al.*, 2000; Goldstein *et al.*, 1991; Hert *et al.*, 1971, 1969, 1972; Lanyon, 1984; O'Connor *et al.*, 1982), and fatigue microdamage (Carter and Hayes, 1976; R. B. Martin and Burr, 1982). In some cases the time-averaged values of these quantities are suggested as the mechanical stimulus, and in others the amplitudes of the oscillatory components and/or peak values of these quantities are the candidates for the mechanical stimulus. Two dozen possible stimuli were compared in a combined experimental and analytical approach (Brown *et al.*, 1990). The data supported strain energy density, longitudinal shear stress, and tensile principal

stress, or strain as stimuli; no stimulus that could be described as rate dependent was among the two dozen possible stimuli considered in the study. For a consideration of the stimulus in microgravity, see Cowin (1998).

The case for strain rate as a remodeling stimulus has been building since the early 1970s. The animal studies of Hert and his coworkers (1971, 1969, 1972) suggested the importance of strain rate. Experiments have quantified the importance of strain rate over strain as a remodeling stimulus (Fritton *et al.*, 2000; Goldstein *et al.*, 1991; Lanyon, 1984). The studies directed at the understanding of the cellular mechanism for bone remodeling have suggested that the prime mover is the bone strain rate–driven motion of the bone fluid whose signal is transduced by osteocytes (Cowin *et al.*, 1995; Weinbaum *et al.*, 1991, 1994). In the model of Weinbaum *et al.* (1991, 1994) the shear stress from the bone fluid flow over the osteocytic processes in the canaliculi is a cellular mechanism–based model, suggesting strain rate as a stimulus. The study of Gross *et al.* (1997), which showed bone deposition to be related to strain gradients by the model of Weinbaum *et al.* (1991, 1994) also demonstrated a dependence on strain rate.

During *in vitro* culture, it has been shown that bone cells exposed to fluid flow respond by displaying increased prostaglandin, nitric oxide (NO), and intracellular  $\text{Ca}^{2+}$  production (Chen *et al.*, 2000; Klein-Nulend *et al.*, 1995a, 1995b), decreased apoptosis (Bacabac *et al.*, 2004; Pavalko *et al.*, 2003a), and rearrangement of junctional proteins (Thi *et al.*, 2003). More specifically, it has been shown that osteocytes, but not periosteal fibroblasts, are extremely sensitive to fluid flow, resulting in increased prostaglandin as well as nitric oxide (NO) production (Klein-Nulend *et al.*, 1995a, 1995b). Three different cell populations — osteocytes, osteoblasts, and periosteal fibroblasts — were subjected to two stress regimes, pulsatile fluid flow (PFF) and intermittent hydrostatic compression (IHC) (Klein-Nulend *et al.*, 1995b). IHC was applied at 0.3 Hz with 13-kPa peak pressure. PFF was a fluid flow with a mean shear stress of 0.5 Pa with cyclic variations of 0.02 Pa at 5 Hz. The maximal hydrostatic pressure rate was 130 kPa/s, and the maximal fluid shear stress rate was 12 Pa/s. Under both stress regimes, osteocytes appeared more sensitive than osteoblasts, and osteoblasts more sensitive than periosteal fibroblasts. However, despite the large difference in peak stress and peak stress rate, PFF was more effective than IHC. Osteocytes, but not the other cell types, responded to 1-hour PFF treatment, with a sustained prostaglandin  $\text{E}_2$  ( $\text{PGE}_2$ ) up-regulation lasting at least one hour after PFF was terminated. By comparison, IHC needed six hours of treatment before a response was found. These results suggested that osteocytes are more sensitive to mechanical stress than are osteoblasts, which are again more sensitive than periosteal fibroblasts. Furthermore, osteocytes appeared particularly sensitive to fluid shear stress, more so than to hydrostatic stress. These conclusions are in agreement with the theory

that osteocytes are the main mechanosensory cells of bone and that they detect mechanical loading events by the canalicular flow of interstitial fluid that results from that loading event. Weinbaum *et al.* (1994) used Biot's porous-media theory to relate loads applied to a whole bone to the flow of canalicular interstitial fluid past the osteocytic processes. Their calculations predict fluid-induced shear stresses of 0.8–3 Pa, as a result of peak physiological loading regimes. The findings that bone cells *in vitro* actually respond to fluid shear stress of 0.2–6 Pa (Hung *et al.*, 1995; Klein-Nulend *et al.*, 1995a, 1995b; Reich *et al.*, 1990; Williams *et al.*, 1994) lend experimental support to the theory.

Prostaglandin is necessary for the new bone formation in response to mechanical loading (Forwood, 1996). It is known that fluid flow induces PGE<sub>2</sub> release, cyclooxygenase 2 (COX-2) expression, gap junction function, and connexin 43 expression in osteocyte-like cells (Cherian *et al.*, 2003). When these cells are exposed to media containing PGE<sub>2</sub>, an increase — similar to that observed in the presence of fluid flow — is observed in the gap junction function and connexin 43 expression. When PGE<sub>2</sub> is depleted from the culture media, this effect is significantly reduced. Therefore, the stimulatory effect of fluid flow on gap junctions is regulated, at least in part, by the release of PGE<sub>2</sub> (Cheng *et al.*, 2001).

Osteocytes also rapidly release NO in response to stress (Klein-Nulend *et al.*, 1995a, 1995b; Pitsillides *et al.*, 1995), and this NO response seems to be required for the stress-related prostaglandin release (Klein-Nulend *et al.*, 1995a). Therefore, the behavior of osteocytes compares to that of endothelial cells that regulate the flow of blood through the vascular system, and also respond to fluid flow of 0.5 Pa with increased prostaglandin and NO production (Hecker *et al.*, 1993). The response of endothelial cells to shear stress is likely related to their role in mediating an adaptive remodeling of the vasculature so as to maintain constant endothelial fluid shear stress throughout the arterial site of the circulation (Kamiya *et al.*, 1984).

Bakker *et al.* (2001) considered the effects of various stimuli (i.e., wall shear stress, streaming potentials, and chemotransport) on the production of both NO and PGE<sub>2</sub> by primary mouse bone cells. By adding dextran to the media, the viscosity, and thereby the shear stress, could be altered without affecting the streaming potentials or chemotransport. This study indicated that shear stress, not streaming potentials or chemotransport, was the stimulus yielding increased NO and PGE<sub>2</sub> production in mouse bone cells (Bakker *et al.*, 2001).

Like osteocytes, osteoblasts release NO and PGE<sub>2</sub> in response to stress (Bacabac *et al.*, 2004; McAllister and Frangos, 1999; Vance *et al.*, 2005). When osteoblasts are subjected to 15 min of fluid shear stress, the resulting NO production is linearly dependent on the fluid shear stress rate, with peak production immediately after the onset of flow (Bacabac *et al.*, 2004). The release of NO in osteoblasts is less sensitive to sustained flow and more sensitive to transients

(McAllister and Frangos, 1999). A rapid increase in intracellular Ca<sup>2+</sup> is also observed in response to shear stress; this intracellular Ca<sup>2+</sup> is thought to be connected to NO release in osteoblasts (Chen *et al.*, 2000; McAllister and Frangos, 1999). Osteoblasts exposed to oscillatory fluid flow (1 Hz) at shear stresses of 1 and 2 Pa resulted in an increase in intracellular Ca<sup>2+</sup> and an increase in the overall percentage of cells responding when a 10- or 15-s rest was added after every 10 loading cycles (Batra *et al.*, 2005).

Fluid shear stress also decreases the apoptosis of osteoblasts (Bakker *et al.*, 2004; Pavalko *et al.*, 2003a). Since these cells are responsible for bone formation, signals that influence osteoblastic apoptosis influence new bone deposition directly. Apoptosis induced in osteoblasts using tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), a molecule known to stimulate bone resorption after menopause, is inhibited by fluid shear stress. TNF- $\alpha$ -induced apoptosis of osteoblasts occurs through a mechanism involving the activation of PI3-kinase signaling and inhibition of caspase-3 (Pavalko *et al.*, 2003a). Another observed effect of fluid shear stress in osteoblast- and osteocyte-like cells is a rearrangement of junctional proteins (e.g., connexin 43 and 45) causing a disruption in junctional communication (Thi *et al.*, 2003).

Skeletal muscle contraction is a typical bone-loading event and has been suggested (Moss, 1968, 1978) as a stimulus. Frequency is one of the critical parameters of the muscle stimulus, and it serves to differentiate this stimulus from the direct mechanical loads of ambulation, which occur at a frequency of 1–2 Hz. The frequency of contracting muscle in tetanus is from 15 Hz to a maximum of 50–60 Hz in mammalian muscle (McMahon, 1984). It has been observed (McLeod and Rubin, 1992; Rodriguez *et al.*, 1993) that these higher-order frequencies, significantly related to bone adaptational responses, are (Rubin *et al.*, 1993) “present within the [muscle contraction] strain energy spectra regardless of animal or activity and implicate the dynamics of muscle contraction as the source of this energy band.” The close similarity of muscle stimulus frequencies to bone tissue response frequencies is noted later.

## Reception and Transduction

The osteocyte has been suggested as the stimulus sensor, the receptor of the stimulus signal (Cowin *et al.*, 1991); histologic and physiologic data are consistent with this suggestion (Aarden *et al.*, 1994). The placement and distribution of osteocytes in the CCN three-dimensional array is architecturally well suited to sense deformation of the mineralized tissue encasing them (Lanyon, 1993). Since only a population of cells, and not an individual receptor (Edin and Trulsson, 1992), can code unambiguously, the osteocytes in the CCN are potential mechanoreceptors by virtue of their network organization.

Osteocytic mechanotransduction may involve a number of different processes or cellular systems. These processes include stretch- and voltage-activated ion channels, cyto-

matrix sensation-transduction processes, mechanosomes, cytosensation by fluid shear stresses, cytosensation by streaming potentials, and exogenous electric field strength. Each of these processes or cellular systems is discussed next.

### Stretch- and Voltage-Activated Ion Channels

The osteocytic plasma membrane contains stretch-activated ion channels (Duncan and Misler, 1989; Guggino *et al.*, 1989; Hamill and McBride, 1996; Keynes, 1994), which are also found in many other cell types (French, 1992; Ghazi *et al.*, 1998; Morris, 1990). When activated in strained osteocytes, they permit passage of certain ions (Sachs, 1986, 1988; Sackin, 1995), including  $K^+$ ,  $Ca^{2+}$ ,  $Na^+$ , and  $Cs^+$ . Such ionic flow may, in turn, initiate cellular electrical events; e.g., bone cell stretch-activated channels may modulate membrane potential as well as  $Ca^{2+}$  ion flux (French, 1992; Harter *et al.*, 1995). Rough estimates of osteocytic mechanoreceptor strain sensitivity have been made (Cowin *et al.*, 1991), and the calculated values cover the morphogenetically significant strain range of 0.1–0.3% in the literature (Lanyon, 1984; Rubin and Lanyon, 1984, 1987). This appears to be too low a strain to open a stretch-activated ion channel. A model involving bone fluid flow has been suggested for the amplification of the 0.1–0.3% strain applied to a whole bone to a value an order of magnitude larger at the osteocytic cytoplasmic process membrane (Cowin and Weinbaum, 1998). Stretch-activated ion channels also occur in osteoblastic cells (Davidson *et al.*, 1990).

As in most cells, the osteocytic plasma membrane contains voltage-activated ion channels, and transmembrane ion flow may be a significant osseous mechanotransductive process (Chesnoy-Marchais and Fritsch, 1988; Ferrier *et al.*, 1991; Jan and Jan, 1992; Ravesloot *et al.*, 1991). It is also possible that such ionic flow generates osteocytic action potentials, capable of transmission through gap junctions (Schirrmacher *et al.*, 1993).

### Cytomatrix Sensation-Transduction Processes

The mineralized matrix of bone tissue is strained when loaded. Macromolecular mechanical connections between the extracellular matrix and the osteocytic cell membrane exist, and these connections may be capable of transmitting information from the strained extracellular matrix to the bone cell nuclear membrane. The basis of this mechanism is the physical continuity of the transmembrane integrin molecule, which is connected extracellularly with the macromolecular collagen of the organic matrix and intracellularly with the cytoskeletal actin. The latter, in turn, is connected to the nuclear membrane (Carvalho *et al.*, 1998; Dolce *et al.*, 1996; Hughes *et al.*, 1993; Ingber, 1998; Janmey, 1998; Meazzini *et al.*, 1998; Richardson and Parsons, 1995; Salter *et al.*, 1997; Shapiro *et al.*, 1995; Shyy and Chien, 1997; Watanabe *et al.*, 1993). It is suggested that such a cytoskeletal lever chain, connecting to the nuclear membrane, can

provide a physical stimulus able to activate the osteocytic genome (D. B. Jones and Bingmann, 1991), possibly by first stimulating the activity of such components as the *c-fos* genes (Dayhoff *et al.*, 1992; Haskin *et al.*, 1993; D. B. Jones and Bingmann, 1991; Machwate *et al.*, 1995; Pavalko *et al.*, 1998a; Petrov and Usherwood, 1994; Sadoshima *et al.*, 1992; Salter *et al.*, 1997; Uitto and Larjava, 1991; N. Wang *et al.*, 1993; Watanabe *et al.*, 1993; Yanagishita, 1993).

A number of studies have investigated the role of the cytoskeleton in fluid shear-induced signaling in bone cells (McGarry *et al.*, 2005; Norvell *et al.*, 2004; Pavalko *et al.*, 1998b; Ponik and Pavalko, 2004). It has been suggested that fluid shear stress leads to increased expression of COX-2 and *c-fos* (Pavalko *et al.*, 1998a) or intracellular  $Ca^{2+}$  (Chen *et al.*, 2000) through mechanisms involving the reorganization of the cytoskeleton. Norvell *et al.* (2004) examined the effect of disruption of the major types of cytoskeletal networks, actin microfilaments, microtubules, and intermediate filaments on fluid shear-induced expression of COX-2 or release of  $PGE_2$ . Using a 90-min steady fluid shear stress, they found that none of the major networks were required for the fluid shear-induced release of  $PGE_2$ . Additionally, intact actin microfilaments and microtubules were not necessary for the fluid shear-induced increase in COX-2 expression (Norvell *et al.*, 2004).

However, the studies of McGarry *et al.* (2005), in contrast with those of Norvell *et al.* (2004), indicated that  $PGE_2$  release in osteocytes exposed to pulsatile fluid flow was significantly decreased when actin microfilaments or microtubules were disrupted. Furthermore, the shear-induced release of  $PGE_2$  from osteoblasts was significantly enhanced when actin microfilaments or microtubules were disrupted. The differences in the results between the studies of Norvell *et al.* (2004) and McGarry *et al.* (2005) were attributed to the differences in the flow profiles: a steady flow profile versus a pulsatile one. Also, the opposite effects of fluid shear on the release of  $PGE_2$  in osteoblasts and osteocytes was hypothesized to be due to differences in the composition of the cytoskeleton of these cell types (osteocyte structure is largely dependent on actin) (McGarry *et al.*, 2005).

In another study, the idea that focal adhesions influence mechanotransduction in osteoblasts was considered (Ponik and Pavalko, 2004). To do so, methods were used to limit formation of focal adhesions: When integrin–fibronectin interactions were blocked, both fluid shear-induced COX-2 expression and  $PGE_2$  release were reduced. These results indicated that focal adhesions were involved in the mechanotransduction of shear-induced signaling, resulting in the release of  $PGE_2$  and the induction of COX-2 (Ponik and Pavalko, 2004).

### Mechanosomes

Pavalko *et al.* (2003b) proposed a model for skeletal mechanotransduction involving *mechanosomes*. This model

hypothesizes that mechanotransduction is a combination of stretch-activated ion channels and cytomatrix sensation-transduction processes. In this model, deformation induced by mechanical loading causes flow through canalicular space, which applies strain to the tissue matrix. Additionally, this flow yields deformation of the membranes of bone cells, causing stretch-activated cation channels to open and resulting in an increase in  $\text{Ca}^{2+}$  in the cytosol.  $\text{Ca}^{2+}$ -dependent kinase cascades are thereby initiated. Simultaneously, the deformation of the membranes causes a conformational change in the membrane proteins. These proteins are linked to a signaling scaffold that releases mechanosomes, protein complexes able to transport mechanical information, into the nucleus, where gene activity is altered (Pavalko *et al.*, 2003b).

### Solitary Cilium as Mechanosensors

It was suggested in 2003 that the solitary cilium on osteoblasts and osteocytes might turn out to be a major mechanosensor in bone (Whitfield, 2003). Recent work has supported that suggestion (Andrews, 2006). Xiao *et al.* (2006) have demonstrated the presence of cilia on osteoblasts and osteocytes and has linked polycystin-1, a protein that associates with cilia and allows them to sense fluid flow in the kidney, with skeletal development in mutant mice. Malone *et al.* (2006) provided preliminary data that loss of cilia resulted in decreased sensitivity to flow. It has not been conclusively demonstrated that these cilia are mechanosensors for osteocytes. It will be important to determine how a single cilium on an osteocyte cell body can mediate the mechanosensory functions ascribed to the osteocyte.

### Cytosensation by Fluid Shear Stresses

A hypothesis concerning the mechanism by which the osteocytes housed in the lacunae of mechanically loaded bone sense the load applied to the bone by the detection of dynamic strains was suggested by Weinbaum *et al.* (1991, 1994). It was proposed that the osteocytes are stimulated by relatively small fluid shear stresses acting on the membranes of their osteocytic processes. A hierarchical model of bone tissue structure that related the cyclic mechanical loading applied to the whole bone to the fluid shear stress at the surface of the osteocytic cell process was presented (Weinbaum *et al.*, 1994). However, an inconsistency in this model was discovered. Specifically, the strains in whole bone are usually less than 0.1% (Fritton *et al.*, 2000; Rubin and Lanyon, 1984); however, mechanical deformation of bone cells *in vitro* requires strains one to two orders of magnitude higher than those measured in whole bone (You *et al.*, 2000). You *et al.* (2001) proposed a model to account for this contradiction. Central to this model is the pericellular space, located between the osteocytic cell process membrane and the canalicular wall, through which bone fluid can flow (You *et al.*, 2001, and references therein). This space is filled by an attached pericellular organic

matrix, supported by transverse fibrils. When whole bone is deformed, the induced pressure gradient will result in bone fluid's entering into this space, inducing a drag force on the pericellular matrix fibrils (You *et al.*, 2001). This drag force is coupled to an intracellular actin cytoskeleton, resulting in strain amplification. For physiological loading ranges, this strain amplification can produce cellular strains that are two orders of magnitude greater than tissue-level strains (less than 0.1%), consistent with levels required for *in vitro* deformation of bone cells. These results suggest that the mechanism for cell stimulation is not direct fluid shear stress, as previously suggested, but, rather, tension from the fibers that traverse the space between the osteocytic cell process and the canalicular wall. The tension in the fibers is a reaction to the drag of the fluid flowing over and through the fibers (Han *et al.*, 2004; You *et al.*, 2001).

Several investigators (Johnson *et al.*, 1982; Kufahl and Saha, 1990; Piekarski and Munro, 1977) have examined other aspects of the lacunar-canalicular porosity using simple circular-pore models and have attempted to analyze its possible physiological importance. These studies have emphasized primarily the importance of the convective flow in the canaliculi between the lacunae as a way of enhancing the supply of nutrients between neighboring osteocytes. Previous studies on the relaxation of the excess pore pressure have been closely tied to the strain-generated potentials (SGPs) associated with bone fluid motion. The SGP studies are briefly reviewed next.

### Cytosensation by Streaming Potentials

The fact that the extracellular bone matrix is negatively charged due to its proteins means that a fluid electrolyte bounded by the extracellular matrix will have a diffuse double layer of positive charges. When the fluid moves, the excess positive charge is convected, thereby developing streaming currents and streaming potentials. The cause of the fluid motion is the deformation of the extracellular matrix due to whole-bone mechanical loading. Pollack and coworkers (Pollack *et al.*, 1984; Salzstein and Pollack, 1987; Salzstein *et al.*, 1987) have laid an important foundation for explaining the origin of strain-generated potentials (SGPs). However the anatomical site in bone tissue that is the source of the experimentally observed SGPs is not agreed on. Salzstein and Pollack (1987) concluded that this site was the collagen-hydroxyapatite porosity of the bone mineral, because small pores of approximately 16-nm radius were consistent with their experimental data if a poroelastic-electrokinetic model with unobstructed and connected circular pores was assumed (Salzstein *et al.*, 1987). Cowin *et al.* (1995), using the model of Weinbaum *et al.* (1994), have shown that the data of Salzstein and Pollack (1987), Scott and Korostoff (1990), and Otter *et al.* (1992) are also consistent with the larger pore space (100 nm) of the lacunar-canalicular porosity as the anatomical source site of the SGPs if the hydraulic drag and electrokinetic contribution

associated with the passage of bone fluid through the surface matrix (glycocalyx) of the osteocytic process are accounted for (Otter *et al.*, 1992; Scott and Korostoff, 1990). The mathematical models of Salzstein *et al.* (1987) and Weinbaum *et al.* (1994) are similar, in that they combine poroelastic and electrokinetic theory to describe the phase and magnitude of the SGP. The two theories differ in the description of the interstitial fluid flow and streaming currents at the microstructural level and in the anatomical structures that determine the flow. In Weinbaum *et al.* (1994) this resistance resides in the fluid annulus that surrounds the osteocytic processes, i.e., the cell membrane of the osteocytic process, the walls of the canaliculi, and the glycocalyx (also called the *surface matrix* or *capsule*) that exists in this annular region. In Cowin *et al.* (1995) the presence of the glycocalyx increases the SGPs and the hydraulic resistance to the strain-driven flow. The increased SGP matches the phase and amplitude of the measured SGPs. In the Salzstein *et al.* (1987) model this fluid resistance and SGP are achieved by assuming that an open, continuous small pore structure ( $\approx 16$ -nm radius) exists in the mineralized matrix. The poroelastic model of Weinbaum *et al.* (1994) for bone fluid flow has been developed further (Zhang *et al.*, 1997, 1998a, 1998b), and a review of the related poroelastic literature has been published (Cowin, 1999).

Experimental evidence indicating that the collagen-hydroxyapatite porosity of the bone mineral is unlikely to serve as the primary source of the SGP is obtained from several sources, including the estimates of the pore size in the collagen-hydroxyapatite porosity and permeability studies with different-size-labeled tracers in both mineralized and unmineralized bone. Such permeability studies clearly show time-dependent changes in the interstitial pathways as bone matures. At the earliest times, the unmineralized collagen-proteoglycan bone matrix is porous to large solutes. Studies with ferritin (10 nm in diameter) in two-day-old chick embryo show a continuous halo around primary osteons five minutes after the injection of this tracer (Dillaman, 1984). The halo passes right through the lacunar-canalicular system, suggesting that, before mineralization, pores of the size predicted in Salzstein and Pollack (1987) (radii  $\approx 16$  nm) can exist throughout the bone matrix. In contrast, Montgomery *et al.* (1988), using this same tracer in adult dogs, also found a fluorescent halo surrounding the Haversian canals (Montgomery *et al.*, 1988); however, this halo was not continuous, but formed by discrete lines, suggesting that the pathways were limited to discrete pores whose spacing was similar to that observed for canaliculi. This conclusion is supported by the studies of Tanaka and Sakano (1985) in the alveolar bone of five-day-old rats using the much smaller tracer microperoxidase (MP) (2 nm) (Tanaka and Sakano, 1985). These studies clearly showed that the MP penetrated only the unmineralized matrix surrounding the lacunae and the borders of the canaliculi (see Fig. 13 of this study) and was absent from the mineralized

matrix. Using more mature rats, the failure of MP (2 nm) and reactive red (1 nm) tracers to penetrate the mineralized matrix tissue from the bone fluid compartments was confirmed (L. Y. Wang *et al.*, 2004).

### Exogenous Electric Field Strength

Bone responds to exogenous electrical fields (Otter *et al.*, 1998). While the extrinsic electrical parameters are unclear, field strength may play an important role (Brighton *et al.*, 1992; Otter *et al.*, 1998). A significant parallelism exists between the parameters of exogenous electrical fields and the endogenous fields produced by muscle activity. Bone responds to exogenous fields in an effective range of 1–10  $\mu\text{V}/\text{cm}$ , strengths that are on the order of those endogenously produced in bone tissue during normal (muscle) activity (McLeod *et al.*, 1993). These exogenous fields are thought to affect the activity of hormones, growth factors, cytokines, and mechanical forces, which, in turn, alter the response of bone cells (Spadaro, 1997).

### Uniqueness of Osseous Mechanosensation

The difference between mechanosensation in bone tissue and mechanosensation in nonosseous processes is revealing and thought to be significant. First, most mechanosensory cells are cytologically specialized (e.g., rods and cones in the retina); bone cells are not. Second, one bone-loading stimulus can evoke three adaptational responses (deposition, maintenance, and resorption), while nonosseous process stimuli evoke just one (e.g., vision). Third, osseous signal transmission is aneural, while all other organismal mechanosensational signals (Moss-Salentijn, 1992) utilize afferent neural pathways (e.g., the visual pathway; Hackney and Furness, 1995). Fourth, the evoked bone adaptational responses are confined within each bone independently (e.g., within a femur); there is no organismal involvement (e.g., touch is a generalized somatic sensation). However, all afferent transductive processes, osseous and nonosseous, share many common mechanisms and processes (Gilbertson, 1998; Wilson and Sullivan, 1998).

### Signal Transmission

From a communications viewpoint, the CCN is multiply noded (each osteocyte is a node) and multiply connected. Each osteocytic process is a connection between two osteocytes, and each osteocyte is multiply connected to a number of osteocytes that are near neighbors (see Fig. 61.1). Cell-to-cell communication is considered first, and then we discuss the opening of hemichannels as a means of transmitting signaling factors. Finally, we speculate on the ability of the CCN to compute as well as signal. It is useful to note the possibility that bone cells, like neurons, may communicate intercellular information by volume transmission, a process that does not require direct cytological contact, but, rather, utilizes charges in the environment (Fuxe and Agnati, 1991; Marotti, 1996; Schaul, 1998).

### Cell-to-Cell Communication

In order to transmit a signal over the CCN, one osteocyte must be able to signal a neighboring osteocyte, which will then pass the signal on until it reaches an osteoblast on the bone surface. There are a variety of chemical and electrical cell-to-cell communication methods (De Mello, 1987). The passage of chemical signals, such as  $\text{Ca}^{2+}$ , from cell to cell appears to occur at a rate that would be too slow to respond to the approximately 30-Hz signal associated with muscle firing. We focus here on electrical cell-to-cell communication. Zhang *et al.* (1997, 1998a) have formulated a cable model for cell-to-cell communication in an osteon. The spatial distribution of intracellular electric potential and current from the cement line to the lumen of an osteon was estimated, because the frequency of the loading and conductance of the gap junction were altered. In this model the intracellular potential and current are driven by the mechanically induced strain-generated streaming potentials (SGPs) produced by the cyclic mechanical loading of bone. The model differs from earlier studies (Harrigan and Hamilton, 1993), in that it pursues a more physiological approach, in which the microanatomical dimensions of the connexon pores, the osteocytic processes, and the distribution of cellular membrane area and capacitance are used to estimate quantitatively the leakage of current through the osteoblast membrane, the time delay in signal transmission along the cable, and the relative resistance of the osteocytic processes and the connexons in their open and closed states. The model predicts that the cable demonstrates a strong resonant response when the cable coupling length approaches the osteonal radius. The theory also predicts that the pore pressure relaxation time for the draining of the bone fluid into the osteonal canal is of the same order as the characteristic diffusion time for the spread of current along the membrane of the osteocytic processes. This coincidence of characteristic times produced a spectral resonance in the cable at 30 Hz. These two resonances lead to a large amplification of the intracellular potential and current in the surface osteoblasts, which could serve as the initiating signal for osteoblasts to conduct remodeling.

### Opening of Hemichannels

As described earlier, it is known that the stimulatory effect of fluid flow on gap junctions and connexin-43 expression is at least partly regulated by the release of  $\text{PGE}_2$  (Cheng *et al.*, 2001). This observation raised the question of how the  $\text{PGE}_2$  molecules (negatively charged at physiological pH) are transported to the cell's exterior. Recently, it has been shown that connexin-43 hemichannels, found in osteocytes and osteoblasts, can be opened by mechanical strain. The opening of these hemichannels was demonstrated to act as a direct route for exit of intracellular  $\text{PGE}_2$  (Cherian *et al.*, 2005, and references therein). This novel mechanism could have important implications for the rapid exit, and thereby the transmission, of other signaling molecules involved in bone adaptive processes.

### Signal Processing and Integration

When a physical representation of a CCN, such as Figure 61.1, is viewed by someone familiar with communications, there is often an intuitive response that the CCN may function as a neural network for processing the mechanical loading stimulus signals being felt over the network. That idea is explored here with no justification other than shared intuition. A CCN is operationally analogous to an artificial neural network in which massively parallel, or parallel distributed, signal processing occurs (Edin and Trulsson, 1992; Martino *et al.*, 1994). Fortunately, the bases of connectionist theory are sufficiently secure to permit a biologically realistic CCN model (Dayhoff *et al.*, 1992; Hinton and Anderson, 1989; McClelland and Rumelhart, 1987; Zornitser *et al.*, 1990).

A CCN consists of a number of relatively simple, densely interconnected processing elements (bone cells), with many more interconnections than cells. Operationally these cells are organized into layers: an initial input, a final output, and one or more intermediate or hidden layers. However, such networks need not be numerically complex to be operationally complex (Kupfermann, 1992).

The operational processes are identical, in principle, for all bone cells in all layers. All cells in any layer may simultaneously receive several weighted (i.e., some quantitative measure) inputs. In the initial layer these are the loading stimuli (mechanoreception). Within each cell independently, "all the weighted inputs are then summed" (Wasserman, 1989). This net sum is then compared, within the cell, against some threshold value. If this liminal value is exceeded, a signal is generated (mechanotransduction in input layer cells) that is then transmitted identically to all the hidden layer cells (adjacent osteocytes) to which each initial layer cell is connected. Similar processes of weighted signal summation, comparison, and transmission occur in these layers until final layer cells (osteoblasts) are reached. The outputs of these surface-situated cells regulate the specific adaptation process of each group of osteoblasts (Parfitt, 1994). All neighboring osteoblasts that carry out an identical bone adaptational process form a communication compartment, a cohort of structurally and operationally similar cells, since all these cells are interconnected by open, functional gap junctions. At the boundary between such compartments that are carrying out different adaptational processes, the intervening gap junctions are closed and are incapable of transmitting information. These boundaries are probably changing continuously because some of the cells have some downtime (Jeansonne *et al.*, 1979; Spray, 1998).

Information is not stored discretely in a CCN, as is the case in conventional computers. Rather, it is distributed across all or part of the network, and several types of information may be stored simultaneously. The instantaneous state of a CCN is a property of all of its cells and of their connections. Accordingly its informational representation

is redundant, ensuring that the network is fault, or error, tolerant; i.e., one or several inoperative cells causes little or no noticeable loss in network operations (Wasserman, 1989).

CCNs exhibit oscillation; i.e., iterative reciprocal (feedback) signaling between layers enables them to self-organize adjustively. This is related to the fact that CCNs are not preprogrammed; rather, they learn by unsupervised training (Fritzke, 1994), a process involving the adaptation of the CCNs to the responses of the cytoskeleton to physical activity (Dayhoff *et al.*, 1992). In this way the CCN adjusts to the customary mechanical loading of the whole bone (Lanyon, 1984). In a CCN, structurally more complex attributes and behavior gradually self-organize and emerge during operation. These are not reducible; they are neither apparent nor predictable from a prior knowledge of the behavior of individual cells.

As noted earlier, gap junctions, as electrical synapses, permit bidirectional flow of information. This is the cytological basis for the oscillatory behavior of a CCN. The presence of sharp discontinuities between groups of phenotypically different osteoblasts is also related to an associated property of gap junctions, i.e., their ability to close and thus prevent the flow of information (Kam and Hodgins, 1992; Kodama and Eguchi, 1994). Significantly, informational networks can also transmit inhibitory signals, a matter beyond our present scope (Marotti *et al.*, 1992).

It is suggested that a CCN displays the following attributes: Developmentally it is self-organized and self-adapting, and, in the sense that it is epigenetically regulated, it is untrained. Operationally it is a stable, dynamic system, whose oscillatory behavior permits feedback; in this regard, it is noted that a CCN operates in a noisy, nonstationary environment and that it also employs useful and necessary inhibitory inputs.

The CCN permits a triad of histological responses to a (seemingly) unitary loading event. Although in this chapter, as in almost all the related literature, the organization of bone cells is treated as if it existed in only two dimensions and as if bone tissue loadings occurred only at certain discrete loci, and that without consideration of loading gradients, the biological situation is otherwise. Given such a loading event, a three-dimensional bone volume, gradients of deformation must exist, and each osteocyte may sense correspondingly different strain properties. Moreover, it is probable that each osteocyte potentially is able to transmit three different signals in three different directions, some stimulatory and some inhibitory; such states have not yet been modeled (Moss, 1997a, 1997b).

#### A Tentative Mechanotransduction Synthesis

The molecular lever mechanisms that permit muscle function to regulate directly the genomic activity of strained bone cells, including their phenotypic expression, when combined together with electric field effects and contrac-

tion frequency energetics, provides a biophysical basis for an earlier hypothesis of epigenetic regulation of skeletal tissue adaptation (Moss, 1962, 1968; Moss and Salentijn, 1969; Moss and Young, 1960).

It is probable (Moss, 1997c, 1997d) that electrical and mechanical transductive processes are neither exhaustive nor mutually exclusive. While utilizing differing intermediate membrane mechanisms and/or processes, they share a common final pathway (Bhalla and Iyengar, 1999); i.e., both mechanical and electrical transductions result in transplasma membrane ionic flow(s), creating a signal(s) capable of intercellular transmission to neighboring bone cells via gap junctions (Cowin *et al.*, 1995; Weinbaum *et al.*, 1994; Zeng *et al.*, 1994; Zhang *et al.*, 1997, 1998a). These signals are inputs to a CCN, whose outputs regulate the bone adaptational processes.

The primacy of electrical signals is suggested here, since while bone cell transduction may also produce small biochemical molecules that can pass through gap junctions, the time course of mechanosensory processes is believed to be too rapid for the involvement of secondary messengers (Carvalho *et al.*, 1994; French, 1992; Wildon *et al.*, 1992). As we noted earlier, the passage of chemical signals, such as  $\text{Ca}^{2+}$ , from cell to cell appears to occur at a rate that would be too slow to respond to the approximately 30-Hz signal associated with muscle firing. The opening of hemichannels in response to mechanical strain could potentially provide a route for rapid release of intracellular signaling molecules.

## IV. MESENCHYMAL STEM CELLS

Osteoblasts and osteocytes are derived from the mesenchymal stem cells (MSCs), found mainly in bone marrow. While much research has focused on the effect of mechanical loading on osteocytes and osteoblasts, the response of these progenitor cells to mechanical stimulation has only recently been explored (Bancroft *et al.*, 2002; Holtorf *et al.*, 2005; Sikavitsas *et al.*, 2003). A perfusion bioreactor was developed to examine the effect of mechanical forces on the differentiation of MSCs in 3D scaffolds for tissue-engineering applications (Bancroft *et al.*, 2002; Sikavitsas *et al.*, 2003). MSCs were cultured for periods of up to 16 days, and markers of osteoblastic differentiation were monitored (alkaline phosphatase activity, osteocalcin and osteopontin secretion, and calcium content); cells cultured in the presence of fluid flow exhibited enhanced osteoblastic differentiation as compared to static controls for all flow conditions tested (perfusion rates varied from 0.3 to 3 mL/min). The effect of the fluid flow on the deposited mineralized matrix was found to be dose dependent and due to fluid shear stress rather than chemotransport (Bancroft *et al.*, 2002; Sikavitsas *et al.*, 2003). Using a cylindrical-pore model, the shear stress experienced by MSCs was estimated to be less than 1 dyne/cm<sup>2</sup>; when the pore size of the scaffold was decreased, thereby reducing the exerted shear stress, greater mineral deposition was observed after 16 days of culture

(Holtorf *et al.*, 2005). These results indicate that fluid shear stress influences the osteoblastic differentiation of MSCs during *in vitro* culture on 3D scaffolds. Additionally, it was demonstrated that MSCs cultured in the perfusion bioreactor deposited an extracellular matrix (ECM) rich in

osteoblastic differentiation factors; fresh MSCs seeded on this ECM showed enhanced osteoblastic differentiation (Datta *et al.*, 2006). Further study is required to investigate the role of fluid flow on MSC differentiation *in vivo* and the signaling pathways affected by exposure to fluid flow.

## V. ACKNOWLEDGMENTS

In the earlier editions of this volume, this chapter was co-authored with Melvin L. Moss (January 3, 1923–June 25, 2006), a passionate scientist and teacher.

### I. INTRODUCTION

As the U.S. population ages, skeletal-tissue injury and loss from trauma or disease exact a burgeoning socioeconomic burden on the health care system. Recent data place U.S. health care expenditures at over \$1.8 trillion (HCUP, 2006). Skeletal-related injuries and diseases represent a significant portion of this cost. According to 2003 data from the U.S. Health Cost and Utilization Project, there were approximately 1 million hospital admissions for appendicular skeletal fractures in the United States, with an aggregate cost of over \$26 billion (HCUP, 2006). Costs for skull and facial fractures contributed an additional \$1.3 billion. Of all fractures, approximately 10% are complicated with impaired healing (Logeart-Avramoglou *et al.*, 2005). Thus, regenerative medicine offers an exciting option for addressing the reconstruction of osseous defects. With the culmination of developments in materials science, bioengineering, stem cell biology, and molecular biology, the potential of tissue engineering to accelerate bone regeneration becomes a distinct possibility.

The clinician is confronted with an array of large bone defects resulting from trauma, resection of malignancies, nonunion of fractures, and congenital malformations. Autografts remain the best option for reconstructing bony defects because they provide the osteogenic cells, osteoinductive factors, and lattice needed for bone regeneration. They can be obtained from the patient's calvarium, ribs, iliac crest, distal femur, greater trochanter, or proximal tibia (Perry,

1999). Autografts, however, subject the patient to the inherent risks of surgery during harvest (Laurencin *et al.*, 2006). In a retrospective study of autografts harvested from the iliac crest, a complication rate nearing 10% was found, including infection, fracture, large hematomas, pain, paresthesia, and nerve injury (Younger and Chapman, 1989). Furthermore, autografts are a relatively scarce resource and are limited by the amount of bone that can be removed without causing undue morbidity to the donor site. In situations where autografts are not sufficient or possible, allogeneic bone, from donors or cadavers, may be used (Laurencin *et al.*, 2006). However, use of allografts is accompanied by the risk for disease transmission, immunologic rejection, and graft-versus-host disease.

Ceramics and metals are the other major categories of bone substitutes available to repair skeletal defects, each with its associated problems. Metals provide immediate mechanical support but fail to integrate with surrounding tissue (Salgado *et al.*, 2004). Metals are also at higher risk for infection and fatigue loading. Ceramics, mimicking the inorganic composition of bone, tend to integrate well but possess low tensile strength and are very brittle (Temenoff and Mikos, 2000). Numerous other synthetic materials have been developed to aid in bone reconstruction, including the use of plaster of Paris, polymer-based substitutes, and bioactive glass.

The wide range of options available for osseous reconstruction is indicative of the many advances made in bio-

materials, but it also reflects the inadequacies of any single method. As such, tissue engineering portends great promise for being able to address more adequately the issue of repairing bone defects. A foretaste of tissue engineering is already in clinical application, in the form of delivering osteogenic cytokines, specifically bone morphogenetic proteins (BMPs), to induce bone formation. The translational goal is ultimately to deliver both osteogenic cells and cytokines via a biologically active scaffold, in order to heal a bony defect in an accelerated fashion.

This chapter begins with an overview of distraction osteogenesis, a modality that translates directed mechanical force into endogenous bone formation, to emphasize the important role of the mechanical environment on bone formation and to highlight the growth factors that play a role in inducing bone formation. This chapter then discusses the necessary components of bone-tissue engineering, cellular sources, osteogenic cytokines, and scaffolds, with an emphasis on recent developments.

## II. DISTRACTION OSTEOGENESIS

Distraction osteogenesis is relevant to tissue engineering because it provides a model for the study of endogenous bone formation in large skeletal defects. First described by Alexander Codivilla in 1905 for limb lengthening and later codified by Gavril Ilizarov in the 1950s, distraction osteogenesis represents an endogenous form of bone-tissue engineering (Codivilla, 1905; Ilizarov, 1989a; Ilizarov, 1989b). New bone is formed during the process of separating osteogenic fronts with gradual but constant mechanical force. As a first step, an osteotomy is usually performed on the bone of interest, followed by application of rigid fixation. This is followed by a latency period of several days, during which a soft callus forms between the two osteogenic fronts. Gradual distraction is then applied, followed by stable fixation, until a stable osseous regenerate is formed. It is thought that the mechanical forces applied by distraction can contribute to bone formation by induction of cytokines that guide mesenchymal cells in the bony gap to differentiate along an osteogenic lineage. Distraction osteogenesis not only triggers bone formation, but also stimulates local angiogenesis as part of the process (Aronson, 1994; Fang *et al.*, 2005).

Much research has been devoted toward characterizing the association between stress and strain patterns with bone formation. Correlating tensile force measurements with histology, Lobo *et al.* (2004) demonstrated that the greatest amount of bone formation occurs during active distraction, the period of greatest strain. Lobo went on further to characterize the forces of distraction, using finite-element analysis models created from three-dimensional computed tomography image data of rat mandibles at different phases of distraction osteogenesis (Lobo *et al.*, 2005). The models described patterns of moderate hydrostatic stress within the gap, predictive of intramembranous ossification, and patterns of mild compressive stress in the periphery, consistent

with endochondral ossification. These data derived from finite-element analysis were consistent with previous histological findings.

Great interest surrounds research characterizing how mechanical forces may be translated into molecular signals that promote bone regeneration. Tong *et al.* (2003) described the role of focal adhesion kinase (FAK), a regulator of the integrin-mediated signal transduction cascade, in distraction osteogenesis. In a rat model of mandible distraction osteogenesis, Tong and colleagues demonstrated immunolocalization of FAK in regions of new bone formation secondary to distraction, which was absent in the control groups, where new bone formation occurred without distraction. Similarly, recent work has also colocalized c-SRC, a kinase involved with activation of the mechanical transduction complex (p130), in regions of bone regeneration secondary to distraction osteogenesis (Rhee and Buchman, 2005). While signaling molecules involved with transduction of mechanical forces are being identified, further work elucidating the mechanisms of these messenger molecules is required to clarify the influence of the mechanical environment on skeletal-tissue engineering.

Distraction osteogenesis has also emphasized the multitude of growth factors that participate in regenerating bone in this environment. Elucidation of their roles and mechanisms in bone regeneration will be a key element in successful tissue engineering. Transforming growth factor  $\beta 1$  (TGF- $\beta 1$ ), a potent growth factor known to stimulate osteoblast proliferation, has been demonstrated, via Northern blot analysis of distracted rat mandibles, to have increased expression after osteotomy, continuing through the distraction period (Mehra *et al.*, 1999). Immunohistochemistry revealed that TGF- $\beta 1$  during the distraction phase is localized to osteoblasts, primitive mesenchymal cells, and the extracellular matrix. Data regarding the effects of exogenous TGF- $\beta 1$ , in general, suggest that it enhances osseous healing (Bouletreau *et al.*, 2002).

Insulinlike growth factor-1 (IGF-1) has also been implicated to play a role in the early stage of distraction osteogenesis. IGF-1 has been shown *in vitro* and *in vivo* to stimulate osteoprogenitor cell mitosis and differentiation (Spencer *et al.*, 1991). In a canine tibia-lengthening model, serum levels of IGF-1 increased initially during the early distraction period, followed by elevations in local IGF-1 levels at the region of distraction (Lammens *et al.*, 1998). Schumacher *et al.* (1996) also presented evidence supporting the role of IGF-1 in early distraction, where periosteal IGF-1 levels in the rat tibia were increased only during active lengthening. Exogenous addition of IGF-1 in a rabbit model of mandible distraction osteogenesis resulted in increased bone formation as compared to control groups (Stewart *et al.*, 1999).

Like TGF- $\beta 1$  and IGF-1, studies have shown fibroblast growth factors (FGFs) to mediate bone formation in distraction osteogenesis. Immunohistochemical staining in a

sheep mandible distraction model revealed FGF-2 staining in the region of distraction, with greater staining in animals with high-rate distraction (Farhadieh *et al.*, 1999). Exogenous administration of recombinant human FGF-2 to a rabbit model of long-bone lengthening, during the end of the distraction period, increased the mineral content of the callus (Okazaki *et al.*, 1999).

Lastly, bone morphogenetic proteins (BMPs), known mediators in bone formation, have been localized to regions of successful distraction osteogenesis. In examining femoral lengthening in rats, gene expression levels of BMP-2 and BMP-4 were found to be elevated during the period of distraction (Sato *et al.*, 1999). Likewise, in distraction osteogenesis of rabbit tibia, immunohistochemical staining revealed intense BMP-2, -4, and -7 staining in fibroblast-like cells and chondrocytes during the distraction phase (Rauch *et al.*, 2000). This was confirmed in membranous bone, where analysis of the bone generated from mandibular lengthening in rabbits revealed BMP-2 and BMP-4 to be highly expressed in osteoblasts during distraction and in chondrocytes during consolidation (Campisi *et al.*, 2003).

Distraction osteogenesis is thus a useful modality for translating discrete applications of mechanical force into molecular signals that induce skeletal regeneration. However, this process is not without its own morbidities, such as soft-tissue infection, osteomyelitis, pintract infection or loosening, and patient discomfort (Mofid *et al.*, 2002). Distraction osteogenesis is also limited by the large hardware necessary to accomplish distraction and by the length of time required for large defects. Given the foregoing, cell-based tissue engineering of bone represents an alternative for addressing large osseous defects.

### III. CRITICAL-SIZED DEFECTS

In the search for optimal elements of successful skeletal-tissue engineering, the critical-sized defect has proved to be an indispensable tool for evaluating the performance of various constructs in an *in vivo* setting. Critical-sized defects are bone defects that fail to heal without intervention. They allow the performance, dosages, and combinations of various cellular sources, osteogenic cytokines, and scaffolds to be evaluated.

Common types of defects include calvarial and long-bone or mandible segmental defects (Salgado *et al.*, 2004). The calvarial model is particularly useful in evaluating constructs for craniofacial defects, given the relative easy handling of the calvarial plate and the support provided by the surrounding intact bone, absolving the need for fixation. It is also a relatively unloaded model mechanically, minimizing the influence of exogenous forces in the investigation of specific cellular elements. Long-bone segmental defects can also be created in the radius, where the ulna provides endogenous fixation of that limb. In situations where load bearing of the construct is desired, femur defects can be used.

These models all allow serial radiographic examination through the use of modalities such as microcomputed tomography. Ultimately, however, histology remains the gold-standard tool in evaluating the efficacy of constructs. Histomorphometric analysis is used to evaluate the amount of new bone formation. Histology also allows for the evaluation of bone resorption, changes in endogenous structure, and quality of the bone regenerate (Salgado *et al.*, 2004). Serving as functional *in vivo* bone regeneration assays, critical-sized defects allow researchers to assess the rate and degree of bone healing for individual components of a bone construct as well as their effect in concert (Cowan *et al.*, 2005).

### IV. CELLULAR THERAPY

Arguably, cells are the most crucial component to skeletal-tissue engineering. The two broad categories of populations available as sources of osteoprogenitor cells include osteoblasts and multipotent cells. At first glance, it would seem that osteoblasts could make a reasonable candidate for bone-tissue engineering. These are cells already committed along a bone lineage and readily form mineralized matrix. However, given the limited number of cells available, their low expansion rate, and donor-site morbidity, the osteoblast population is not an ideal cellular source for skeletal-tissue engineering (Heath, 2000).

As such, stem cells appear to be the most promising option for regenerative medicine. Stem cells are defined as a population of cells with the ability for prolonged division while undifferentiated, as well as the ability to differentiate along multiple lineages with the proper biological cues (Thomson *et al.*, 1998). Stem cells of embryonic origin have the most plasticity along the totipotent hierarchy. By definition, they are able to differentiate along all three embryonic germ layers: the endoderm, the ectoderm, and the mesoderm (Thomson *et al.*, 1998). The ability of embryonic stem cells to differentiate into osteoblasts and bone was demonstrated *in vitro* with murine embryonic stem cells, in the presence of dexamethasone (Buttery *et al.*, 2001). However, because of the ethical and political controversy surrounding the use of embryonic stem cells, researchers have focused their attention on postnatal sources of multipotent cells (Bahadur, 2003; Chin, 2003; Weissman, 2002).

Postnatal stem cells have been identified in bone marrow, periosteum, muscle, fat, brain, skin, and umbilical cord blood (Salgado *et al.*, 2004). Although discussion continues as to the degree of their differentiation potential, research in this area has been spurred by the capacity of these postnatal progenitor cells to differentiate along multiple lineages. The most commonly studied source of postnatal stem cells is the bone marrow. The major components of bone marrow are hematopoietic and mesenchymal stromal cells. The hematopoietic component provides the progenitors that will differentiate into all the mature blood cell phenotypes. Bone marrow mesenchymal stem cells

(BMSCs) are easily isolated from the hematopoietic components because of their unique quality to adhere to polystyrene culture dishes. Substantial work has demonstrated the ability of BMSCs to be guided along multiple mesenchymal lineages, including bone, cartilage, muscle, ligament, tendon, and stroma (Kadiyala *et al.*, 1997; Pittenger *et al.*, 1999, 2000). BMSCs have been shown, *in vitro*, to differentiate along an osteogenic pathway when cultured in the presence of dexamethasone, ascorbic acid, and  $\beta$ -glycerophosphate (Kadiyala *et al.*, 1997; Pittenger *et al.*, 1999).

The use of BMSCs in skeletal-tissue engineering has been demonstrated in multiple animal models. Oghushi and colleagues (1989) implanted bone marrow cells loaded on calcium phosphate ceramics into critical-sized defects of rat femurs. They demonstrated a higher rate of complete bone union and accelerated healing in the bone marrow cell group as compared to controls. Similar results were shown by Bruder *et al.* (1998), where human BMSCs, seeded on a ceramic carrier, were implanted into femur defects of athymic rats. Defects with BMSC implants healed and were significantly stronger under mechanical loading conditions than defects implanted with cell-free ceramics. In a rabbit calvarial model, BMSCs seeded on a fibrin scaffold demonstrated osseous regeneration similar to control implants seeded with osteoblasts (Schantz *et al.*, 2003).

Although the concept of BMSCs is attractive for tissue engineering, it is limited by the low frequency of mesenchymal stem cells within bone marrow stroma. Analysis of human bone marrow aspirates have found that the incidence of BMSCs can be as low as 1 in 27,000 cells (Banfi *et al.*, 2000). Furthermore, the procedure of acquiring bone marrow is a painful one, requiring general or local anesthesia. Other limitations on the use of BMSCs include the need for sera and growth factor supplements for *in vitro* expansion prior to use (Baksh *et al.*, 2003). Although subject to debate, BMSCs from older animals have been observed *in vitro* to form less bone than that from young animals, although this may be a reflection of their differences in proliferative ability (Bergman *et al.*, 1996).

Recently, a mesenchymal cell population has been isolated from the stromal component of adipose tissue (AMC) and has been demonstrated to be multipotent (Lin *et al.*, 2006; Zuk *et al.*, 2001). Zuk *et al.* described isolating an adherent cell population from human adipose tissue and inducing these cells to differentiate along adipogenic, chondrogenic, osteogenic, and myogenic lineages. Comparison of CD marker antigens demonstrated a similar expression profile between AMCs and BMSCs (Zuk *et al.*, 2002). Osteogenic differentiation conditions were found to be identical to that for BMSCs, supplementing media with dexamethasone,  $\beta$ -glycerophosphate, and ascorbate-2-phosphate. Confirmation of osteogenic differentiation was obtained with alkaline phosphatase and von Kossa staining as well as expression of bone-related genes, including Cbfa-1, alkaline phosphatase, osteopontin, and osteocalcin (Zuk *et al.*, 2002).

This finding is significant because AMCs are an abundant multipotent cell population that can be procured from individuals with minimal morbidity, expanded fairly rapidly, and used in an autologous fashion for tissue regeneration or reconstruction (Aust *et al.*, 2004; De Ugarte *et al.*, 2003; Zuk *et al.*, 2002, 2001).

Lee *et al.* (2003) demonstrated the ability of AMCs to differentiate into bone, *in vivo*, by seeding polylactic glycolic acid (PLGA) scaffolds with predifferentiated AMCs from Lewis rats and implanting them subcutaneously. Bone formation was demonstrated eight weeks later by tissue morphology on hematoxylin-eosin staining and immunohistochemical staining for osteocalcin.

The efficacy of AMCs in healing osseous defects was demonstrated in a model of critical-sized calvarial defects in mice (Cowan *et al.*, 2004). Implanting AMCs seeded on hydroxyapatite-coated PLGA scaffolds into calvarial defects, significant bone formation was demonstrated by x-ray, histology, and molecular imaging. At two weeks, significant bone formation was seen in the defect, with complete bony bridging by 12 weeks. Comparison of defects implanted with AMC-seeded scaffolds versus BMSC-seeded scaffolds demonstrated similar rates of bone formation. This experiment established an important proof of principle that AMCs contributed to bone formation in a critical-sized, skeletal defect in mice.

Interestingly, although AMCs from young mice demonstrated a greater ability to proliferate, AMCs from young and old mice both exhibited robust osteogenic differentiation (Shi *et al.*, 2005). This observation may be attributed to the presence of BMP-2 and retinoic acid in the osteogenic differentiation media for mouse AMCs, accounting for the continued ability of AMCs from adult animals to display robust osteogenic differentiation. This finding is encouraging because it suggests that, with the proper cues, cells from aging animals are still able to maximize their potential for bone formation.

Thus, the mesenchymal stem cell (MSC) population seems to be a very promising cellular candidate for promoting skeletal regeneration. MSCs derived from fat are especially attractive because of their ease of procurement, the abundance of MSCs derived from a harvest, and their rapid expansion. Whether MSCs are derived from bone marrow or adipose tissue, they still remain a heterogeneous population that remains to be fully characterized. Future direction in developing a cellular source for skeletal-tissue engineering includes the need to identify markers of a mesenchymal progenitor cell subpopulation that possesses the strongest proclivity for osteogenic differentiation.

## V. CYTOKINES

The study of bone formation in developmental biology and distraction osteogenesis has revealed a host of growth factors involved with this process. Research on these cytokines has provided much information on the effect of these

signaling molecules on cell proliferation, differentiation, adhesion, migration, and ultimately bone formation. An understanding of these interactions will undoubtedly allow for their use in bone-tissue engineering. It is foreseeable that successful skeletal-tissue engineering will involve the incorporation of the appropriate cytokines with an osteoprogenitor population.

Already in use clinically, BMPs seem to be the most promising candidate cytokine in skeletal-tissue engineering. BMPs, members of the TGF- $\beta$  superfamily, were originally isolated by Urist from bovine bone extracts and found to induce ectopic bone formation subcutaneously in rats (Urist, 1965). This large group of proteins, comprising nearly one-third of the TGF- $\beta$  superfamily, has also been found to be involved in mesoderm induction, skeletal patterning, and limb development (Duprez *et al.*, 1996). BMPs are known to control both intramembranous as well as endochondral ossification through chemotaxis and mitosis of mesenchymal cells, induction of mesenchymal commitment to osteogenic or chondrogenic differentiation, and programmed cell death (Reddi, 2001). BMPs transmit their signals via ligand binding to the heteromeric complex of types I and II serine/threonine kinase receptors on the cell surface (Shi and Massague, 2003). The ligand signal is then transduced intracellularly via activation of SMAD (signaling, mothers against decapentaplegic) proteins, which subsequently migrate to the nucleus to effect gene expression (Noth *et al.*, 2003). BMP signaling has also been demonstrated to be transmitted via the MAP-kinase (mitogen-activated protein) pathway (Gallea *et al.*, 2001).

BMP-2, -4, -6, -7, and -9 are known to be the most osteoinductive (Jadlowiec *et al.*, 2003). It is thought that BMPs regulate osteoblast differentiation via increased transcription of core-binding factor-1/Runx-related family 2 (Cbfa1/Runx2), a molecule known to be necessary for commitment along an osteoblastic lineage (Ducy *et al.*, 1997; Gu *et al.*, 2004; Harada *et al.*, 1999; Otto *et al.*, 1997; Tou *et al.*, 2003). These osteoinductive BMPs have all been demonstrated to stimulate osteogenic differentiation in multiple cell lines, including fibroblasts, chondrocytes, BMSCs, and AMCs. The effect of BMPs has also been noted to be concentration dependent. At low concentrations, they foster chemotaxis and cellular proliferation (Zimmerman *et al.*, 1996). At high concentrations, BMPs induce bone formation (Urist, 1997). BMPs are more potent at inducing bone formation as heterodimers than as homodimers. In culture, BMP-2/6, BMP-2/7, and BMP-4/7 heterodimers have been shown to promote higher alkaline phosphatase levels than homodimer combinations (Aono *et al.*, 1995). These data have also been corroborated *in vivo* (Israel *et al.*, 1996).

FGFs are a highly conserved family of 24 peptides, which transmit their signal via a family of four transmembrane tyrosine kinases. FGF-2, the most abundant ligand of the family, is known to increase osteoblast proliferation and to enhance bone formation *in vitro* and *in vivo* (Kimoto

*et al.*, 1998; Nakamura *et al.*, 1997). In FGF-2-haploinsufficient and -null mice, decreased bone mineral density was observed grossly and correlated with decreased expression of FGF receptor-2 and Runx2 at a molecular level (Naganawa *et al.*, 2006). Exogenous FGF-2 was able to rescue decreased bone nodule formation in osteoblast cultures from these transgenic mice.

IFG-1 and IGF-2 are 7.6-kDa polypeptides that have been demonstrated to stimulate bone collagen synthesis as well as osteogenesis and chondrogenesis (Linkhart *et al.*, 1996). In a transgenic mouse, where IGF expression was specifically up-regulated in osteoblasts, there was increased bone formation of the distal femur as compared to control mice (Zhao *et al.*, 2000). Of interest, however, is that histology did not reveal an increase in the number of osteoblasts, suggesting that IGF-1 up-regulated the activity of existing bone-forming cells. Conversely, in an IGF-1-null, transgenic mouse model, the size and bone-formation rates of the knockout mice were significantly reduced as compared to their wild-type littermates (Bikle *et al.*, 2002).

Platelet-derived growth factor (PDGF), a 30-kDa polypeptide, has also been demonstrated to be a potent stimulus for osteoblast proliferation, chemotaxis, as well as collagen activity. The utility of PDGF *in vivo* has also been shown, with enhanced bone formation after local application of PDGF to tibial osteotomies in rabbits and canine mandibles after periodontal surgery. PDGF, commonly used in chronic wounds, is now being studied clinically in periodontics. Nevins *et al.* (2005), in a multicenter, randomized, controlled trial, demonstrated that the application of recombinant human PDGF in a tricalcium phosphate matrix significantly increased periodontal bone formation.

While the bulk of tissue-engineering applications involve the utilization of BMPs, multiple other cytokines exist for potential use in skeletal-tissue regeneration. The intuitive approach for delivery of cytokines involves incorporation of these molecules into scaffolds. Recent work, however, has explored the possibility of utilizing microspheres and liposomes as delivery mechanisms. This system would allow the growth factor to be retained at the site of interest for an extended period while maintaining its biological activity (DiTizio *et al.*, 2000). The process of creating microspheres involves combining the cytokine, which is dissolved in aqueous phase, with a polymer, which is dissolved in an appropriate solvent (Borden *et al.*, 2002). The combination of these two solutions is then dispersed into another aqueous phase, which serves to create the microspheres. This emulsion is heated to evaporate the solvent. The microspheres are then isolated by centrifugation and sintered for scaffold formation.

The delivery of cytokines in this encapsulated form has been examined in several animal models. Woo *et al.* (2001) described encapsulating recombinant human BMP-2 within PLGA microspheres and implanting them in rat calvarial defects. Compared to a control group with an immediate-

release formulation, the microsphere group demonstrated sustained release of BMP-2 and greater amounts of bone matrix formation. Similar results have been demonstrated in a long-bone model with the delivery of recombinant human BMP-7 in PLGA microspheres to a critical-sized, ulna defect in rabbits (Borden *et al.*, 2004).

The challenges of incorporating cytokines in skeletal-tissue engineering involve identifying molecules whose actions are specific to bone formation. Other issues requiring further work include the timing of delivery, effective dosages, and compatible carrier mechanisms. Study of these growth factors *in vitro* and in critical-sized defect models will help provide answers to these questions.

## VI. SCAFFOLDS

Paralleling research on an ideal osteoprogenitor cell population and the identification of potential cytokines for bone-tissue engineering, advances in materials science have provided an abundance of innovations on developing an appropriate carrier for these cells and molecules. In the selection of a biomimetic scaffold for engineering bone, the material should be osteoconductive, osteoinductive, biocompatible, and biodegradable. *Osteoconductivity* refers to the ability of the graft to support the attachment of cells and allow new cell migration and vessel formation. The *osteoinductive* quality of scaffolds describes their ability to induce nondifferentiated stem cells or progenitor cells along an osteogenic lineage. The scaffold should not elicit an immune response. In examining the structure of scaffolds, maximizing the porosity of the scaffold, to promote cellular and neo-vascular ingrowth, must be balanced by respect for the structural integrity of the lattice (Salgado *et al.*, 2004). Given the foregoing, an overview of the scaffolds available currently ensues in relation to these criteria. These matrices can be generalized into three categories: natural, mineral based, and synthetic polymers.

Natural scaffolds include the use of collagen, hyaluronic acids, calcium alginate, and chitosan (Bumgardner *et al.*, 2003; Cho *et al.*, 2005; Saadeh *et al.*, 2001; Seol *et al.*, 2004; Solchaga *et al.*, 2002). Natural scaffolds are typically biodegradable. In many instances, they exhibit osteoinductive properties, exclusive of cells or cytokines. Implantation of collagen type I alone into critical-sized defects of rat mandibles resulted in healing (Saadeh *et al.*, 2001). The disadvantage of natural scaffolds is their lack of mechanical stability and, hence, ability to be used in load-bearing regions of the skeleton. Use of natural scaffolds in humans is also limited by the biochemical changes often induced by sterilization procedures (Zahraoui and Sharrock, 1999).

Mineral-based scaffolds include calcium phosphate ceramics and bioactive glass. Calcium phosphate ceramics are available as hydroxyapatite or  $\beta$ -tricalcium phosphate, with hydroxyapatite most closely mimicking the structural and chemical characteristics of the mineral component of bone (Nacamuli and Longaker, 2005). Tricalcium

phosphate is marked by a high dissolution rate that accelerates material resorption and elicits an immune response. In contrast, hydroxyapatite has high chemical stability. In general, mineral-based scaffolds provide an osteoinductive signal to encourage differentiation of progenitor cells along an osteogenic lineage. There is, however, great variability in the quality of calcium phosphate ceramics to support osteogenesis. This is due to the difficulty in reproducibly creating these scaffolds (El-Ghannam and Ning, 2006).

Polymer scaffolds, including polylactic acid, polyglycolic acid, polydioxanone, and polycaprolactone, have been engineered to provide a greater ability to withstand mechanical forces. These lattices are marked by their incredible strength (Behraves *et al.*, 1999; Ishaug *et al.*, 1997). They are also designed to be biodegradable via hydrolysis as a result of their local milieu. Polymer scaffolds allow ingrowth of bony tissue, but they lack osteoinductive properties. Thus, current work is focused on combining polymer formulations with hydroxyapatite or growth factors, which would encourage cellular osteogenic differentiation.

Hydrogels represent another class of polymer scaffolds. They are formed by polymerization and cross-linking of molecules such as acrylic acid, and *N*-isopropylacrylamide (Stile *et al.*, 1999). Hydrogels are an attractive option because of their temperature-dependent physical properties. They can be designed to be gelatinous at room temperature, but they take on more rigid qualities at body temperatures (Stile and Healy, 2002). This property could allow for the administration of tissue-engineering constructs via injection. Hydrogels also allow for relatively easy chemical manipulation of individual peptides. Incorporation of arginine-glycine-aspartic acid (RGD) peptide motifs on these polymers has been demonstrated to enhance osteoblast adhesion and proliferation (Rezania and Healy, 1999).

Recently, electrospinning has emerged as a novel method to construct scaffolds that more closely mimic natural extracellular matrix. Electrospinning involves creation of nanowoven fibers by shooting a jet of polymer solution through a high electric field (Li *et al.*, 2006). Adjusting the polymer solution and the electric field allows the fiber diameter and porosity to be controlled (Zong *et al.*, 2003). The advantage of this technique is not only that it mimics ECM, but that various pro-osteogenic materials or cytokines can be incorporated more conveniently into this scaffold. Li *et al.* (2006) incorporated BMP-2 and nanoparticles of hydroxyapatite into silk fibroin fiber scaffolds using this technique. They demonstrated, *in vitro*, higher mineralization of human MSCs cultured on these scaffolds than in controls.

## VII. ANGIOGENESIS

Another frontier of work that has emerged is providing the bone construct with a vascular supply. In hostile cellular microenvironments, such as large defects, irradiated regions, and contaminated wounds, blood flow to the implanted

bone graft could increase its performance and survival. Fukui *et al.* (2005) provided bone-forming constructs, consisting of human MSCs and osteogenic cytokines in a gelatin carrier, with blood flow from an epigastric flap. Implants provided with a vascular source formed higher bone mineral density than those that were not.

Without a vascular supply, osseous constructs depend on diffusion to supply the necessary nutrients and to remove metabolic waste. Especially in large defects, the diffusion process is limited by an effective distance of 150–200  $\mu\text{m}$  from blood vessels (Colton, 1995). Furthermore, hypoxic conditions are known to contribute to the significant attrition rates of MSCs *in vitro* (Logeart-Avramoglou *et al.*, 2005).

One avenue of research that may provide a solution to this problem is the delivery of angiogenic molecules that could accelerate vascular invasion of the implanted bone construct. Vascular endothelial growth factor (VEGF), a 34- to 46-kDa homodimeric glycoprotein known to be an essential regulator of angiogenesis, is a potential candidate (Ferrara, 2000; Ferrara *et al.*, 2003; Fong *et al.*, 1996). The VEGF family consists of placental growth factor (PLGF), VEGF-B, VEGF-C, and VEGF-D. They bind to three homologous high-affinity transmembrane receptors: VEGF-R1 (Flt-1), VEGF-R2 (Flk-1), and VEGF-R3 (Flt-4). The role of VEGF in endochondral bone formation was demonstrated in neonatal mice by the systemic application of mouse Flt(1-3)-IgG, a soluble, VEGF-receptor, chimeric protein that would competitively bind to VEGF (Gerber *et al.*, 1999). This experimental approach resulted in suppressed capillary invasion, impaired cartilage remodeling, and defective bone formation. VEGF expression is found in bone fracture-healing sites and growth plates and is thought to regulate the migration of endothelial cells to sites of osseous regeneration (Jadlowiec *et al.*, 2003).

Current experiments involving the delivery of VEGF to regions of osseous regeneration have met with mixed results. In a model of distraction osteogenesis of rabbit tibias, animals treated with VEGF at the bony defect demonstrated increased blood flow but did not demonstrate increased bone formation at the site (Eckardt *et al.*, 2003). In a recent experiment by Huang and colleagues (2005), bone formation of various PLGA constructs was evaluated following a period of subcutaneous implantation in SCID mice. PLGA implants contained combinations of human BMSCs and plasmid DNA-encoding BMP-4 or VEGF. Scaffolds containing VEGF-encoding plasmids demonstrated a significant increase in blood vessel formation. The combination of all three components in one scaffold exhibited the greatest amount of osseous regeneration. While this experiment contained many confounding variables, it suggests that increased blood vessel formation with other appropriate components may aid in more robust bone formation. Given the critical role of VEGF in endochondral ossification, further work could more appropriately examine the effect of adding VEGF to cell-seeded scaffolds, with respect to healing of skeletal defects of varying sizes.

## VIII. TISSUE ENGINEERING IN PRACTICE

While the goal of bone-tissue engineering is to incorporate an osteoprogenitor cell population with the necessary cytokines on a biomimetic matrix, current clinical applications of tissue engineering involve only the delivery of cytokines, namely recombinant human BMP-2 and BMP-7. A significant criticism of these applications is the high doses necessary to obtain clinical relevance and the resultant costs associated with manufacturing recombinant human BMPs. Concern also exists about the rare but reported incidences of high blood pressure and even myocardial infarctions in animal models, which could be explained by an immunologic response to the cytokines (Cowan *et al.*, 2005).

The Infuse® Bone Graft/LT Cage® fusion device is currently in use for skeletally mature patients with degenerative disc disease at one level from L4-S1 (Medtronic Sofamor Danek, Minneapolis, MN). This product involves an absorbable, bovine collagen implant soaked with recombinant human BMP-2 (rhBMP-2). Humans require supraphysiologic doses ranging from 0.4 to 1.5 mg/mL of rhBMP-2 to form new bone. Because of the high doses, there have been concerns of uncontrolled bone growth around the implantation site or cancer, given links of osteosarcoma with BMP activity (Raval *et al.*, 1996; Yoshikawa *et al.*, 1994). A recent clinical study of Infuse® in 74 consecutive patients revealed radiographic fusion was 100% at 12 and 24 months. No bone overgrowth or sarcomas were observed. The study was significantly weakened, however, by the lack of a control group (Villavicencio *et al.*, 2005).

rhBMP-2 has also been used in patients requiring maxillary sinus floor augmentation, in preparation for endosseous dental implants. Recombinant human BMP-2, on an absorbable collagen sponge, at 0.75 and 1.5 mg/mL, was applied to the maxillary sinus floor. Radiographic evaluation for increases in bone mass in the maxillary sinus floor revealed that rhBMP-2 was able to induce bone formation, but it was not as effective as autogenous bone grafting in fostering osseous formation. Notably, though, rates of successful placement of dental implants were similar between the bone graft treatment arm and those that received rhBMP-2 (Boyne, 2001).

The other product approved by the FDA for clinical use is recombinant human BMP-7 (rhBMP-7) (Stryker Orthopedics, Mahwah, NJ). It is also delivered via a bovine collagen matrix and has been approved for the treatment of nonunion in the tibia of at least nine months, secondary to trauma, in skeletally mature patients. Recombinant human BMP-7 has been approved only for use in cases where previous treatment with autograft failed. In a recent small-series report, the use of rhBMP-7 in five patients who had failed allografts did not result in any significant healing (Delloye *et al.*, 2004). Recombinant human BMP-7 has also been in clinical use to aid intertransverse process fusion in the lumbar spine (Vaccaro *et al.*, 2005). In a putty formulation

consisting of rhBMP-7, bony fusion rates were comparable to groups treated with autograft. They did not report any adverse events, ectopic bone formation, or systemic toxicities associated with use of this product over a two-year period.

## IX. CONCLUSION

The intersection of advances in stem cell biology, molecular biology, biochemistry, bioengineering, and materials sciences has brought to the forefront the nearing reality of regenerative medicine in addressing problems of skeletal defects. Efforts are encouraged by the further understanding of the functions and interactions of osteogenic cytokines as well as by the identification of postnatal osteoprogenitor cells in bone marrow and adipose tissue. The influence of nanotechnology on scaffold design and the possibility of

sustained-release formulations of growth factors via microspheres are promising developments.

Work remains to be performed on further elucidation of the mechanisms of the multitude of osteogenic cytokines as well as on developing effective delivery systems for these molecules to avoid the need for supraphysiologic doses. Efforts also need to be directed toward developing methods to provide vascular perfusion of large osseous constructs, potentially through the use of pro-angiogenic agents. In the realm of stem cell biology, the need for identifying characteristics of an enriched osteoprogenitor population also represents an area requiring further investigation. Given the immense biomedical burden of skeletal defects and the significant developments in skeletal-tissue engineering, osseous regeneration provides a promising and attainable goal that can be achieved only through interdisciplinary collaboration.

### I. INTRODUCTION

This chapter summarizes the current state of neural stem cell research, with a particular focus toward applications in regenerative medicine and tissue engineering. The text highlights the close relationship between developmental biology and neural stem cell biology and discusses techniques for isolation, characterization, and differentiation of neural stem cells. Protocols for the neural differentiation of mouse and human embryonic stem cells are also presented. Numerous examples are provided to direct ES cells toward specific neuronal or glial fates. Finally, current and future applications of neural stem cells are discussed, and the advantages of ES cell-derived primary and endogenous neural stem cells are compared. Neural stem cell biology has grown into a discipline with powerful novel tools and techniques. Neural stem cells will become an essential instrument to unraveling basic questions related to brain development, providing a unique cellular interface with tissue-engineering approaches and working toward the promise of medical breakthroughs.

For most of the last century the thought of applying tissue-regeneration and -engineering principles to the central nervous system was considered naive and unrealistic. The neuroscience community was under the strong influence of the famous neuroanatomist Ramon Y Cajal, who stated that (in the adult central nervous system) “everything may die, nothing may be regenerated.” Interestingly,

however, in the very same paragraph Ramon Y Cajal also wrote that “it is for the science of the future to change, if possible, this harsh decree.” After nearly a century of failures, the time may have come to take on this challenge. Today a number of novel tools are available that have fundamentally changed our ability to approach CNS regeneration and disease, to apply principles of tissue engineering, and to make steps toward the ultimate dream of applying CNS repair to the diseased brain. Among the key developments that have made this possible is the discovery that the adult brain continues to harbor a reservoir of neural stem cells that may be harnessed for repair, the ability to culture primary neural stem and progenitor cells *in vitro*, and the ability systematically to direct cell fate from mouse and human embryonic stem cells.

We begin with a brief introduction to neural development and then cover neural stem cells, addressing the current advantages and limitations of these cells. Then we deal with the derivation of neural cells from embryonic stem cells, followed by a more general discussion of neural stem cell applications in tissue engineering, developmental biology, disease modeling, and regenerative medicine.

### II. NEURAL DEVELOPMENT

Neural induction occurs during gastrulation via “organizer” signals emanating from the node and notochord and acting on the overlying dorsal ectoderm. While the initial

work by Speamann and Mangold (1924) suggested the presence of a direct neural inducer signal, experiments performed over half a century later led to the conclusion that neural induction occurs during early gastrulation by a default mechanism (Munoz-Sanjuan and Brivanlou, 2002). The default model suggests that key molecules capable of inducing neural fate act via inhibiting BMP signaling. These include Chordin (Sasai *et al.*, 1995), Noggin (Lamb *et al.*, 1993), Follistatin (Hemmati Brivanlou *et al.*, 1994), and cerberus. Recent studies suggest that FGF signals emanating from precursors of the organizer prior to gastrulation contribute to a prepattern of neural induction via activation of Sox3 and ERNI (Streit *et al.*, 2000). However, experiments in *Xenopus* suggest that FGF signaling may exert proneural activity, in part via activating MAPK and leading to inhibition of BMP signaling via SMAD1 phosphorylation (Kuroda *et al.*, 2005; Pera *et al.*, 2003). Other major pathways involved during neural induction are IGF (Pera *et al.*, 2001, 2003) and Wnt signaling (Baker *et al.*, 1999; Wilson *et al.*, 2001).

Neural plate cells undergo a set of morphological and molecular changes leading to neural fold and neural tube formation and closure. These morphogenetic events are followed by orchestrated waves of neural proliferation and differentiation. Neural fate specification is highly dependent on regional signals specific to the anteroposterior (AP) and dorsoventral (DV) locations within the embryo, translating into distinct subdomains defined by the combinatorial expression of homeodomain and bHLH transcription factors. There is considerable evidence for the hypothesis that anterior neural fates are established by default while posterior fates require exposure to caudalizing signals such as FGF, Wnt, Nodal, and retinoids during neural induction (for review, see Lumsden and Krumlauf, 1996). The combinatorial action of these caudalizing signals may further subdivide the CNS into discrete AP domains (Nordstrom *et al.*, 2006). DV patterning involves the dose-dependent antagonistic action of the secreted molecules sonic hedgehog (SHH) and BMP (for review, see Jessell, 2000). SHH is expressed ventrally in the notochord and floor plate, while BMPs are secreted dorsally from the roof plate. There is ample evidence from explant (Ericson *et al.*, 1995; Roelink *et al.*, 1995; Ye *et al.*, 1998) and ES cell differentiation studies (Barberi *et al.*, 2003; J. Y. Kim *et al.*, 2002; S.-H. Lee *et al.*, 2000; Mizuseki *et al.*, 2003; Wichterle *et al.*, 2002) supporting a concentration-dependent role for SHH for generating ventral CNS fates (Briscoe *et al.*, 2000). However, genetic studies in SHH mutant embryos, including the SHH/Gli3 (Litington and Chiang, 2000; Persson *et al.*, 2002; Rallu *et al.*, 2002) or SHH/Rab23 mice (Eggenchwiler *et al.*, 2001), suggest that DV patterning can occur in the absence of SHH.

The role for BMPs in driving dorsal CNS fates is supported by various *in vitro* studies in explant culture and by multiple ES cell differentiation protocols (Liem *et al.*, 1995, 1997; Mizuseki *et al.*, 2003). However, genetic studies again suggest a more complex picture. Loss-of-function studies

via the ablation of the roof plate (K. J. Lee *et al.*, 2000), and gain-of-function studies via expression of the BMP receptor type 1a (BMPRIa/Alk3) under control of the nestin enhancer (Panchision *et al.*, 2001) are compatible with a dose-dependent role for BMPs in dorsal patterning. However, loss of the BMP receptor (BMPRIa) results in the loss of choroid plexus fates without obviously affecting other dorsal cell fates (Hebert *et al.*, 2002) and the loss of the dl1 and dl2 domains in the spinal cord (Wine-Lee *et al.*, 2004). Similar to the ventral spinal cord, the dorsal spinal cord can be subdivided into distinct progenitor domains, defined by the combinatorial expression of specific bHLH factors, and homeodomain proteins, with dorsal precursor domains marked by Olig3 expression (Muller *et al.*, 2005).

Region-specific neural fates are adopted in a sequential manner, leading to appropriate neuron subtypes and followed by astroglial and oligodendroglial differentiation. Neuronal differentiation is mediated by inhibition of the Notch pathway, repressing proneural bHLH genes (for review, see Gaiano and Fishell, 2002; Tanigaki *et al.*, 2001). Subsequent astrocytic fates require the activation of the Jak/STAT pathway, exerting an instructive role on multipotent neural progenitors to drive astrocytic differentiation (Bonni *et al.*, 1997; Rajan and McKay, 1998). However, recent insight into the neurogenic properties of radial glial (Noctor *et al.*, 2002) cells and the identification of adult neural stem cells expressing astrocytic markers (Doetsch *et al.*, 1999) suggest a more complex and dynamic interaction between neural stem cell and astrocytic fates. Similarly, our current understanding of the developmental origin of oligodendrocytes has undergone significant changes. Early studies suggested that oligodendrocytes are derived from bipotent glial precursors termed *O2A progenitors* (Ffrench-Constant and Raff, 1986) or from other glially committed precursors (Rao *et al.*, 1998). However, more recent studies reported a direct lineage relationship between motoneuron and oligodendrocytes (He *et al.*, 2001; Lu *et al.*, 2002; Yung *et al.*, 2002; Zhou and Anderson, 2002) based on Olig2 expression. Oligodendrocyte progenitor cells (OPCs) arise from the ventricular zone (VZ) of the embryonic spinal cord (for review, see Rowitch, 2004) and ganglionic eminences in the forebrain (Kessaris *et al.*, 2006). While most Olig2<sup>+</sup> oligodendrocyte progenitors emanate from the ventral CNS, recent work has also demonstrated Olig2<sup>+</sup>/PDGFRa<sup>+</sup> progenitors located with the dorsal spinal cord (Cai *et al.*, 2005; Vallstedt *et al.*, 2005).

### III. NEURAL STEM CELLS

#### Isolation

The presence of neural stem cells in the CNS has been debated for decades. Persistent neural precursor cells in adult mammalian CNS were described by Altman and Das (1965) more than 40 years ago. However, the idea of a stem cell-like population in the mammalian CNS was largely ignored at that time. Subsequent work, in the early 1980s, provided convincing evidence of persistent neurogenic

populations in the adult canary brain (Goldman and Nottebohm, 1983) and showed a clear link between dividing ventricular zone precursor cells and postmitotic neurons derived from these precursor populations using pulse chase  $H^3$ -thymidine labeling. Parallel studies were performed describing in detail all the dividing precursor populations in the developing rat CNS (Frederiksen and McKay, 1988). Technical limitations in manipulating stem cells *in vivo* required the development of *in vitro* assays. Early efforts demonstrated the isolation of precursor populations and early attempts aimed at manipulating cell fate (Cattaneo and McKay, 1990). A key step in the explosive growth of neural precursor cell studies was the development of the neurosphere culture system (Gritti *et al.*, 1995; Kilpatrick and Bartlett, 1993; Reynolds and Weiss, 1992). Under neurosphere conditions, neural precursors are proliferated free-floating in the presence of EGF or FGF2. Human neurosphere cultures are often supplemented with LIF in addition to EGF and FGF2 (Galli *et al.*, 2000). Neurospheres can be derived clonally, and the capacity for neurosphere formation has been used as an assay to determine neural stem cell identity. The prospective isolation of neural stem cells based on the expression of AC133 (Uchida *et al.*, 2000), Lex1 (Capela and Temple, 2002), or combinations of surface markers (Rietze *et al.*, 2001) was largely based on neurosphere formation capacity. However, such data need to be interpreted cautiously, for neurosphere formation is not a true test of stemness. Neurospheres are heterogeneous structures and in the adult SVZ are obtained at higher efficiencies from transient amplifying cells than from the presumptive SVZ stem cells (Doetsch *et al.*, 2002).

An alternative approach is the growth of neural stem-like cells as monolayer cultures in the presence of FGF2 on plates precoated with fibronectin or laminin (Davis and Temple, 1994; Johe *et al.*, 1996; Palmer *et al.*, 1995). These conditions are amenable to determining precise lineage relationships and manipulations at the single-cell level. Complete lineage trees for single cortical stem cells have been defined under such conditions (Qian *et al.*, 2000). More recent work suggests that the combination of FGF2 and EGF in monolayer cultures improves the ability of long-term expanded precursors to undergo neuronal fate specification. Such symmetrically dividing neural stem cell populations express markers of radial glia and are capable of differentiating into GABAergic neurons and glutamatergic neurons after more than 100 population doublings (Conti *et al.*, 2005).

## Characterization

### Clonal Assays, Self-Renewal, and Differentiation Potential

Over 10 years of intensive research has convincingly demonstrated self-renewal and multilineage differentiation of rodent neural stem cells. Clonal cultures have been a key assay for these studies. However, similar assays in human neural stem cells have been technically challenging, and

there are very few examples of clonal human neurosphere cultures from primary unmodified neural stem cells. Another major challenge in neural stem cell biology has been the inability to properly control neuronal subtype specification. While many tissue-specific stem cells, such as hematopoietic stem cells, are capable of differentiation into most if not all progeny within an organ system (Spangrude *et al.*, 1988), long-term expanded neural stem cells do not efficiently give rise to all neuronal subtypes but are largely limited to the production of GABA and glutamatergic neurons (Caldwell *et al.*, 2001; Jain *et al.*, 2003). The derivation of midbrain dopamine neurons has served as a model for these difficulties. Functional midbrain dopamine neurons can be derived from short-term expanded precursors isolated from the early rodent and human midbrain (Sanchez-Pernaute *et al.*, 2001; Studer *et al.*, 1998). However, long-term expansion causes a dramatic drop in the efficacy of midbrain dopamine neuron generation (J. Yan *et al.*, 2001). Several strategies based on intrinsic and extrinsic fate induction have been developed in an effort to overcome these problems (see later). However, none of these approaches has succeeded in deriving unlimited numbers of midbrain dopamine neurons that exhibit full functionality. The mechanisms responsible for the restricted neuronal subtype potential remain to be elucidated. The subtypes most difficult to generate are neurons born during limited temporal windows in early development. This suggests that competent precursors capable of dopaminergic differentiation may be lost during expansion or that required noncell autonomous cofactors are missing in expanded cultures. It is well known that mitogens such as FGF2 can deregulate neural patterning states in precursor cell cultures (Gabay *et al.*, 2003). Epigenetic factors such as methylation and histone modification also influence neural fate specification, such as neuronal and astrocytic fate choice (Hsieh *et al.*, 2004; Song and Ghosh, 2004). Many of the basic regulators of neural stem cell fate and differentiation, such as the NRSF complex and the polycomb gene BMI, involve epigenetic modifications (Ballas *et al.*, 2005; Valk-Lingbeek *et al.*, 2004). Future strategies to overcome neuronal subtype restrictions in neural stem cells may include isolating neural stem cells at an earlier developmental state under conditions that retain early competency, the induction of competence in later precursors using extrinsic cues, or direct manipulation of the epigenetic state. These challenges are major roadblocks to the use of neural stem cells in neurodegenerative disorders such as Parkinson's disease (PD) and amyotrophic lateral sclerosis (ALS; also called Lou Gehrig's disease).

## Differentiation and Plasticity

### Neurons

There is a clear stage-dependent bias in the ability of neural precursor cells to yield neuronal progeny. While precursors at early developmental stages produce neurons exclusively, later precursors show mixed neuronal/glial dif-

ferentiation progressing toward a glial bias in the postnatal and adult brain. Various strategies have been developed to drive neuronal differentiation from multipotent precursors. Factors shown to enhance neuronal fate specification in embryonic rat neural precursors and in human neurosphere progeny are PDGF (Caldwell *et al.*, 2001; Johe *et al.*, 1996) and neurotrophic factors, including NT3 and NT-4/5 (Caldwell *et al.*, 2001; Vicario-Abejon *et al.*, 1995). Adult-derived hippocampal precursors show enhanced neuronal differentiation after exposure to a combination of retinoic acid and neurotrophins (Takahashi *et al.*, 1999), though overall neuronal yield in these cultures remains low. Interestingly, both PDGF and neurotrophic factors have also been shown to promote oligodendroglial fates under different circumstances (Calver *et al.*, 1998; Marmur *et al.*, 1998). A common requirement of neuronal differentiation is the activation of proneural bHLH factors. Indeed, the forced expression of bHLH factors in neural precursors drives neuronal specification and inhibits glial differentiation (Nieto *et al.*, 2001).

#### Midbrain DA Neuron Differentiation

Dopamine neuron differentiation has been an obvious target for neural stem cell research, given the long history of experimental cell transplantation in Parkinson's disease (PD). One of the first examples of generating midbrain dopamine neurons *in vitro* came from studies based on the isolation of neural precursor cells from the developing midbrain. These cells can be propagated *in vitro* in serum-free medium in the presence of FGF2. Differentiation by growth factor withdrawal leads to the generation of large numbers of midbrain DA neurons capable of reversing behavioral deficits after transplantation into the striatum of PD rats (Studer *et al.*, 1998). While such studies were encouraging, they also showed clear limitations of the midbrain precursor system. While DA neuron differentiation was highly efficient in precursors proliferated for short *in vitro* culture periods, long-term expanded precursors rapidly lost the ability to generate midbrain DA neuron progeny, despite intact neuronal differentiation potential (J. Yan *et al.*, 2001). Many groups subsequently tried to overcome these limitations with modified culture protocols, such as the use of ascorbic acid during differentiation, culture of midbrain precursors under reduced oxygen levels (Studer *et al.*, 2000), cocktail of growth factors (Carvey *et al.*, 2001; Storch *et al.*, 2001) thought to enhance DA neuron differentiation potential, or, most recently, the use of various Wnt signaling molecules (Castelo-Branco *et al.*, 2003) or TGF $\beta$ -related molecules (Farkas *et al.*, 2003). Genetic strategies to drive DA neuron fates in neural precursors of nonmidbrain origin include expression of Nurr1 alone (J. Y. Kim *et al.*, 2003; Wagner *et al.*, 1999) or in combination with bHLH factors or SHH and BclXL (Park *et al.*, 2006), the latter strategy resulting in DA neurons capable of survival and function *in vivo*. While some of these strategies provide clear improvements in our

ability to control DA neuron differentiation in neural stem cells, the levels of improvement remain modest, and cell identity may not always correspond to bona fide midbrain DA neuron.

#### Motoneurons

Motoneurons are born during a brief developmental window early in development. There is limited evidence that motoneurons can be generated from neural stem cells. While there are data on the derivation of cholinergic neurons from human neurospheres via SHH priming (Wu *et al.*, 2002), these findings have not been confirmed in independent studies. Short-term expansion of embryonic spinal cord precursors followed by motoneuronal fate specification has been demonstrated (Mayer-Proschel *et al.*, 1997), but, similar to the midbrain DA neuron problem just discussed, it is limited to restricted precursor cells after short expansion rates only.

#### Other Neuron Subtypes

Recent work comparing the properties of FGF2-expanded neural precursor cells isolated from the adult hippocampus and the adult hypothalamus suggested that both populations can yield comparable neuronal subtypes after differentiation (Markakis *et al.*, 2004). This study concluded that neuronal fates are at least in part plastic and controlled *in vivo* by environmental factors that restrict neuronal fate to region-appropriate subtypes, while such restricted fates are accessible *in vitro*. Similar plasticity has been suggested after expansion and *in vitro* proliferation of forebrain precursor cells when implanted into ectopic environments (Hitoshi *et al.*, 2002).

#### Glia

##### Astrocytes

Astrocytic differentiation of multipotent neural stem cells has served as one of the key paradigms of fate specification via an extrinsic signaling factor. It has been shown that similar to the O2A progenitors cells, multipotent neural stem cells undergo rapid and highly efficient astrocytic differentiation in response to CNTF (Johe *et al.*, 1996). It has been further shown that CNTF acts via activation of STAT3 and that the response can be blocked using a dominant negative inhibitor of STAT signaling (Bonni *et al.*, 1997; Rajan and McKay, 1998). However, CNTF astrocytic differentiation in response to CNTF is dependent on the appropriate developmental stage, and early neural precursors such as E12 rat forebrain cells do activate STATs in response to CNTF but do not yield astrocytic progeny (Molne *et al.*, 2000). The responsiveness to LIF seems to correlate with the expression of the EGFR (Viti *et al.*, 2003). Another signaling pathway that is capable of promoting astrocytic fates under appropriate conditions is the BMP pathway (Gross *et al.*, 1996).

### Oligodendrocytes

Thyroid hormone (T3) has been one of the key factors to regulate oligodendroglial fates from neural stem cells (Johe *et al.*, 1996). Other factors that promote oligodendroglial differentiation or proliferation include SHH (Lu *et al.*, 2000; Pringle *et al.*, 1996), PDGF (Barres *et al.*, 1993), and neurotrophic factors, particularly NT3 (Barres *et al.*, 1994).

### Non-CNS Fates

One example of neural stem cell plasticity is the ability to yield neural crest-like progeny after exposure to FGF2 and BMPs (Sailer *et al.*, 2005). The derivation of neural crest-like populations has also been reported from the adult SVZ. These cells exhibit a migratory behavior *in vivo* similar to that of neural crest precursors (Busch *et al.*, 2006). Examples of neural stem cell differentiation into nonneural progeny include the *in vitro* differentiation of skeletal muscle-like cells (Valtz *et al.*, 1991). Other reports on the differentiation of neural stem cells into nonectodermal derivatives such as blood (Bjornson *et al.*, 1999) and the pluripotent behavior of neural stem cells after transplantation into the early blastocyst (Clarke *et al.*, 2000) remain controversial and have not been independently confirmed.

## IV. EMBRYONIC STEM CELL-DERIVED NEURAL STEM CELLS AND NEURAL PROGENY

ES cells are capable of virtually unlimited *in vitro* proliferation and offer many important advantages for both basic and applied research. These include ease of genetic manipulation, access to the earliest stages of neural development, and the comprehensive differentiation potential. Neural differentiation has become one of the most utilized *in vitro* differentiation assays in ES cell research, due to the high efficiency of obtaining neural progeny and the large number of important basic and preclinical applications. The use of ES cells in regenerative medicine became a distinct possibility with the isolation of human ES and embryonic germ (EG) cells (Reubinoff *et al.*, 2000; Shamblott *et al.*, 1998; Thomson *et al.*, 1998).

### Neural Induction

The first step in generating neural subtypes from ES cells is neural induction. There are at least three basic strategies to achieve neural induction: embryoid-body-(EB) based protocols, stromal feeder-mediated neural induction, and protocols based on default differentiation into neural fates.

#### Embryoid Body-Based Protocols

EBs are formed through aggregation of ES cells in suspension cultures. Cell interactions within the EB mimic the

signaling events in normal development, particularly gastrulation. Therefore EB cultures typically result in derivatives of all three germ layers (Doetschman *et al.*, 1985; for review, see Weiss and Orkin, 1996), and EB formation is often used as evidence for pluripotency. While the derivation of neural progeny is inefficient under basic EB conditions, a number of protocols have been developed to enhance neural induction and to select and expand EB-derived neural precursors. The first EB-mediated neural differentiation protocol was based on exposure to retinoic acid (RA) for four days after four days of RA-free culture (4-/4+ protocol) (Bain *et al.*, 1995). Many variations on the basic protocol have been developed (Fraichard *et al.*, 1995; Renoncourt *et al.*, 1998; Strübing *et al.*, 1995). While no clear mechanistic understanding of the action of RA in EBs has emerged, there seems to be a requirement for Wnt inhibition during the process (Aubert *et al.*, 2002; Verani *et al.*, 2006). One major concern in RA-based neural induction protocols is the concomitant effect of RA on AP patterning mediated through activating the Hox gene cascade (Krumlauf, 1994). An alternative EB-based strategy is the exposure to conditioned medium derived from the hepatocarcinoma cell line (HepG2), which appears to induce neuroectodermal fate directly (Rathjen *et al.*, 2002). Accordingly, HepG2-treated aggregates do not express endodermal or mesodermal markers but give rise directly to neural progeny expressing progenitor markers such as Sox1, 2, and nestin. The active component within HepG2-conditioned medium remains to be isolated. Unlike the RA protocols, HepG2 conditions are not thought to bias neural subtype composition toward specific AP or DV fates. A third strategy for achieving neural induction is an RA-free EB-based protocol that subjects EB progeny to neural-selective growth conditions (Brustle *et al.*, 1999; S. H. Lee *et al.*, 2000; Okabe *et al.*, 1996). Neural selection from EB progeny is achieved under minimal-growth conditions in a serum-free medium supplemented with insulin, transferrin, and selenite (ITS medium). These conditions select for immature neural cells expressing the intermediate filament nestin. These nestin<sup>+</sup> precursors can be replated and directed toward various neuronal and glial fates using a combination of patterning, survival, and lineage-promoting factors. Commercial kits have become available that provide all the necessary reagents for this approach. However, ES cell line-specific variability in neural induction efficiency has been observed, particularly at stage III of differentiation (selection of nestin<sup>+</sup> precursors from EBs in ITS medium) (Barberi *et al.*, 2003; Wakayama *et al.*, 2001). Another strategy for neural induction is based on the serum-free EB protocols (SFEBs). This strategy is based on aggregating feeder-free cultures of ES cells under serum-free conditions. The technique is particularly useful for the derivation of forebrain fates (Watanabe *et al.*, 2005). Both classic EB and SFEB protocols have been adapted for use in primate and human ES cells (Schulz *et al.*, 2004; Zhang *et al.*, 2001).

### Stromal Feeder-Mediated Neural Induction

Bone marrow-derived stromal cell lines have been used for many years to support the growth of undifferentiated hematopoietic stem cells (Collins and Dorshkind, 1987; Croisille *et al.*, 1994; Nakano *et al.*, 1994; Sutherland *et al.*, 1991), acting in part via expression of the membrane protein mKlrre, a mammalian homolog of the gene *kirre* of *Drosophila melanogaster* (Ueno *et al.*, 2003). More recently, it has been reported that many of the stromal cell lines that support hematopoietic stem cell growth exhibit neural-inducing properties in coculture with mouse ES cells (Barberi *et al.*, 2003; Kawasaki *et al.*, 2000, 2002). Stromal cell lines with the highest efficiencies of neural induction are typically at the preadipocytic stage of differentiation. While most of these cell lines were isolated from the bone marrow (e.g., PA-6, MS5, S17), stromal cells derived from the aorta-gonad-mesonephros (AGM) region were found to induce neural differentiation equally well in mouse ES and nuclear transfer ES cells (Barberi *et al.*, 2003). While the molecular nature of this stromal-derived inducing activity remains largely unknown, the efficiency and robustness of neural induction via this approach is extremely high (Barberi *et al.*, 2003). There is some controversy as to the extent that feeder-mediated induction biases regional specification or neuronal-versus-glial fate choice (Barberi *et al.*, 2003; Mizuseki *et al.*, 2003; Watanabe *et al.*, 2005). However, the system can be readily adapted to the differentiation of human embryonic stem cells (Perrier *et al.*, 2004) and modified to yield a number of specific neuronal or glial cell types (Perrier *et al.*, 2004; Tabar *et al.*, 2005).

### Neural Differentiation by Default

Coculture-free direct neural differentiation protocols are based on the default hypothesis proposing that in the absence of cell-cell signaling, particularly in the absence of BMPs, ectodermal cells will adopt a neural fate (Munoz-Sanjuan and Brivanlou, 2002). A number of ES cell studies demonstrated that under minimal conditions in the absence of BMP, neural induction does occur in nonadherent (Tropepe *et al.*, 2001) or adherent (Ying *et al.*, 2003) monocultures. Loss-of-function studies suggest an early role for FGFs during neural induction of ES cells, as suggested by studies *in vivo* (Streit *et al.*, 2000). However, the efficacy of default monoculture approaches in comparison to EB and stromal feeder protocols has not been determined. A variation of this protocol was recently suggested to generate fairly homogeneous populations of radial glial-like cells capable of undergoing differentiation to presumptive cortical pyramidal-like cells (Bibel *et al.*, 2004). Subsequent work demonstrated that ES cell-derived radial glial-like cells can be maintained long term in the presence of FGF2/EGF and that these symmetrically dividing precursors retain neurogenic potential over extended *in vitro* cultures (Conti *et al.*, 2005). Most of these cells appear to undergo GABAergic and glutamatergic differentiation compatible with forebrain characteristics. The ability of these cells to yield neuronal

cell types specific to other regions, such as midbrain DA neurons or spinal cord motoneurons, has not been demonstrated.

### Neural Stem Cells

An important issue relates to the question of whether ES cell-derived neural precursor cells exhibit properties of bona fide neural stem cells. Evidence on the multipotent nature of mouse ES cell-derived neural precursors was obtained in clonal studies following single-cell progeny after neural induction proliferation and differentiation of ES progeny. These studies demonstrated clonal derivation of neuronal, astrocytic, and oligodendrocytic progeny comparable to primary neural stem cells (Barberi *et al.*, 2003). Neural stem cell behavior was also observed in long-term expanded ES-derived neural progeny maintained in the presence of FGF2/EGF (Conti *et al.*, 2005). In human ES cells, neural stem cell-like behavior was illustrated *in vivo* after transplantation of human ES-derived neural progeny into the rat striatum or SVZ (Tabar *et al.*, 2005). These cells were capable of integrating in the adult rodent SVZ, expressing markers of SVZ stem cells and transit-amplifying cells, and migrating along the rostral migratory stream to the olfactory bulb. Human-derived olfactory bulb neurons were detected expressing markers comparable to those derived from endogenous rat SVZ neural stem cells.

### Neuronal and Glial Differentiation

#### ES-Derived Neurons

Neuronal differentiation occurs rapidly on neural induction of mouse ES cells. Neuronal subtype specification can be influenced by the neural induction strategy, such as the use of RA, stromal feeders, or SFEB protocol. Strategies to direct neuronal subtype differentiation are based on the application of signals that mimic early patterning events in the embryo to define AP and DV domains within the body axis of the developing embryo.

#### Midbrain Dopaminergic Neurons

Protocols for the dopaminergic differentiation of mouse ES cells closely follow findings obtained in explant studies that identified FGF8 and SHH as critical factors in midbrain dopamine neuron specification (Hynes *et al.*, 1995a, 1995b; Ye *et al.*, 1998, 2001). The effect of SHH/FGF8 on ES-derived neural precursors was first described using an EB-based five-step differentiation protocol (S. H. Lee *et al.*, 2000). Under these conditions up to 34% of all neurons expressed tyrosine hydroxylase (TH), the rate-limiting enzyme in the synthesis of dopamine. A further increase in dopamine neuron yield was obtained in ES cells overexpressing Nurr1 (J. H. Kim *et al.*, 2002). Nearly 80% of all neurons express TH under these conditions, and expression of midbrain dopaminergic markers remains stable even after transgenic expression of Nurr1 has been silenced. Midbrain dopaminergic differentiation was also obtained using coculture of

ES cells on the stromal feeder cell line (PA6) (Kawasaki *et al.*, 2000). PA6 cell-mediated neural induction yielded dopaminergic differentiation in up to 16% of all neurons, without requiring any exposure to exogenous SHH and FGF8 but in the presence of AA. When combining stromal feeder-mediated neural induction with exposure to SHH/FGF8, about 50% of all neurons express TH (Barberi *et al.*, 2003), without requiring any transgene such as *Nurr1* to further push dopamine neuron phenotype. Very similar results can be obtained with primate and human ES cells (Cibelli *et al.*, 2002; Kawasaki *et al.*, 2002; Perrier *et al.*, 2004; Y. Yan *et al.*, 2005).

The numbers of TH neurons need to be interpreted carefully in all *in vitro* differentiation studies because TH is an unreliable marker for identifying dopamine neurons. TH is also expressed in other catecholaminergic neurons, including noradrenergic and adrenergic cells, and it is induced under various extrinsic conditions, such as cell stress, hypoxia, and growth factors. It is therefore essential that studies reporting on the derivation of midbrain dopamine neurons provide additional markers and evidence of dopamine neuron function *in vitro* and *in vivo* (for review, see Perrier and Studer, 2003). The derivation of TH neurons has also been achieved using a monolayer default neural induction protocol (Ying *et al.*, 2003). However, efficiency of dopamine neuron induction, characterization of midbrain phenotype, and *in vitro* and *in vivo* functionality using the default neural induction protocol were not reported. Most recent studies suggest that transgenic expression of the transcription factor *Lmx1A* can increase DA neuron yield in such monolayer cultures. *Lmx1A* expression under control of the nestin enhancer elements in combination with SHH/FGF8 treatments leads to midbrain DA neuron conversion of most ES cell progeny (Andersson *et al.*, 2006). Future studies will be required to compare directly the properties of DA neurons induced genetically versus those induced by purely epigenetic means using extrinsic cues only.

### Serotonergic Neurons

The developmental origin of serotonergic neurons is closely related to that of midbrain dopamine neurons. Both neuronal subtypes are dependent on signals emanating from the isthmic organizer (Goridis and Rohrer, 2002). Accordingly, serotonergic neurons are a major “contaminating” neuronal subtype in protocols aimed at the derivation of midbrain dopaminergic cells. Protocols designed specifically to increase serotonergic versus dopaminergic differentiation have been based on exposure to FGF4. Application of exogenous FGF4 preceding FGF8 and SHH application ectopically induces serotonergic neurons in explant culture (Ye *et al.*, 1998). While application of FGF4 to neural precursors in the presence of FGF2 at stage IV (neural precursor cell proliferation) of the multistep EB differentiation protocol does not yield a significant increase in serotonergic differentiation (S. H. Lee *et al.*, 2000), FGF4 added in the absence of FGF2 does cause a dramatic shift from dopaminergic to

serotonergic differentiation (J. H. Kim *et al.*, 2002). Efficient derivation of hindbrain serotonergic neurons using stromal feeder-mediated neural induction also involves early FGF4 exposure in the absence of FGF2, followed by FGF2, FGF8, and SHH application (Barberi *et al.*, 2003). Novel strategies to refine serotonergic differentiation protocols might make use of novel basic developmental insights that demonstrated the importance of the transcription factor *Lmx1b* in serotonergic differentiation (Ding *et al.*, 2003).

### Motor Neurons

The development of spinal motor neurons has been studied in great detail (for review, see Jessell, 2000; S. K. Lee and Pfaff, 2001). Early studies in mouse ES cells demonstrated that cells expressing markers of motoneurons can be generated using an EB induction protocol in combination with RA exposure (2–/7+) (Renoncourt *et al.*, 1998). More systematic approaches using RA exposure in combination with exogenous SHH to promote ventral fates have yielded ES-derived motoneurons at high efficiency and provided a demonstration on how developmental pathways can be harnessed to direct ES cell fate *in vitro* (Wichterle *et al.*, 2002). By creating an ES cell line that expresses GFP under the control of the motor neuron-specific gene *HB9*, these ES cell-derived motor neurons could also be readily identified and purified. The *in vivo* properties of ES-derived motoneurons were demonstrated on transplantation into the spinal cord of early chick embryos. ES-derived motoneurons were detected in the ventral spinal cord, extended axons, and innervated nearby muscle targets (Wichterle *et al.*, 2002). Efficient derivation of motoneurons can also be achieved using stromal feeders (Barberi *et al.*, 2003; Mizuseki *et al.*, 2003) in combination with SHH and RA treatment. The next challenges for *in vitro* motoneuron differentiation protocols will be the selective generation of motoneurons of distinct AP and columnar identity. Insights from developmental biology studies will provide a good starting point toward that end (Dasen *et al.*, 2003, 2005; Sockanathan *et al.*, 2003). Recent studies in mouse ES cells suggested that the RA/SHH protocols yield primarily cervical and brachial phenotypes of medial motor column identity (Soundararajan *et al.*, 2006). Human ES cell derivation of motoneuron progeny has been demonstrated using an EB-based differentiation strategy followed by exposure to SHH/RA (X. J. Li *et al.*, 2005), and isolation of motoneuron progeny was achieved using transient transfection with an *HB9* enhancer-driven GFP reporter construct (Singh *et al.*, 2005).

### GABA Neurons

GABA cells are the main inhibitor neuron type within the brain and are found at high densities in basal forebrain structures, particularly in the striatum. The presence of GABAergic neurons during ES cell differentiation *in vitro* has been reported under various conditions, including the classic 4–/4+ EB-based differentiation protocols (Bain *et al.*,

1995), which yield approximately 25% GABA neurons (Gottlieb, 2002). Interestingly, protocols with shorter periods of RA-free EB formation followed by extended RA treatment (2–/7+) select for motoneurons rather than GABA neurons (Renoncourt *et al.*, 1998). This suggests that the timing of RA application might be crucial for neural fate specification. The presence of GABA neurons has also been reported under default neural induction conditions (Ying *et al.*, 2003). Differentiation directed to GABA neurons has been achieved using a stromal feeder–based approach (Barberi *et al.*, 2003). Neural induction on MS5 is followed by neural precursor proliferation in FGF2 and subsequent exposure to SHH and FGF8. The delayed application of FGF8 and SHH promotes ventral forebrain identities, as determined by the expression of the forebrain-specific marker FOXG1B (BF-1) (Tao and Lai, 1992) and the increase in GABAergic differentiation (Barberi *et al.*, 2003). In addition to forebrain striatal and cortical GABA neurons there are many other types of GABA neurons in various brain regions, including the thalamus (Houser *et al.*, 1980), midbrain (Ribak *et al.*, 1976), and cerebellum (Hatten *et al.*, 1984). A recent example of the generation of a region-specific GABA neuron type is the derivation of forebrain GABA neurons (Watanabe *et al.*, 2005). GABAergic neuron subtypes of particular clinical relevance may be cortical interneurons for the treatment of intractable epilepsy and medium spiny GABA neurons in Huntington's disease.

### Glutamate Neurons

Glutamate neurons can be readily obtained from mouse ES cells. For example, in the Bain protocol (Bain *et al.*, 1995) approximately 70% of all neurons are glutamatergic, and ES-derived neurons with NMDA and non-NMDA receptor subtypes have been described (Finley *et al.*, 1996). Very similar neuron subtype compositions have been obtained with various related protocols (Strübing *et al.*, 1995; Wernig *et al.*, 2002). More detailed physiological data on glutamatergic neurons have been reported after coculture of ES-derived neurons on hippocampal brain slices (Benninger *et al.*, 2003). Interestingly, this study suggested a possible bias toward establishing AMPA- versus NMDA-type synaptic contacts (Benninger *et al.*, 2003). There is currently no detailed data on the derivation of glutamatergic neurons using stromal feeder protocols. However, default neural differentiation protocols appear efficient at yielding cortical-type glutamatergic neurons derived from radial glial-like precursors (Bibel *et al.*, 2004). Cerebellar granule cells have been induced in an SFEB culture–based system on exposure to BMP4 and Wnt3A (Su *et al.*, 2006).

### Other Neuronal and Neural Subtypes

The presence of about 5% glycinergic neurons has been reported using the classic 4–/4+ EB protocol (Bain *et al.*, 1995; Gottlieb, 2002). However, directed differentiation into this main inhibitory neuronal subtype in the spinal cord has

not been demonstrated. Other interesting neural types generated from ES cells are precursors of the otic anlage (H. Li *et al.*, 2003). These precursors were obtained by culturing EBs for 10 days in EGF and IGF, followed by FGF2 expansion. After transplantation of these precursors, *in vivo* differentiation was observed into cells expressing markers of mature hair cells (H. Li *et al.*, 2003). Derivation of radial glial cells from mouse ES cells (Bibel *et al.*, 2004; Conti *et al.*, 2005; Liour and Yu, 2003) provides another interesting assay system to probe neuronal and glial lineage relationships in early neural development. Cell fates related to eye development, including lenslike precursors (Ooto *et al.*, 2003) and retinal ganglion cells (Ikeda *et al.*, 2005a), have been reported. The efficiency of generating eye-related fates is high in primate and human ES cells. For example, a recent study reported highly efficient differentiation toward retinal fates in human ES cells following simple exposure to factors that promote anterior CNS fates, including IGF1, Noggin, and Dkk (Lamba *et al.*, 2006).

### ES-Derived Glia

Neural precursors derived from mouse ES cells can be readily differentiated into astrocytic and oligodendroglial progeny under conditions similar to those described for primary neural precursors. The first reports on the glial differentiation of mouse ES cells were based on the 4–/4+ EB protocols (Bain *et al.*, 1995; Fraichard *et al.*, 1995; Strübing *et al.*, 1995) or multistep EB differentiation protocols (Okabe *et al.*, 1996). Most of the glial progeny under these conditions are astrocytes, with only a few immature oligodendrocytes present. However, subsequent studies have defined conditions for the selective generation of both astrocytes and oligodendrocytes.

### Oligodendrocytes

Highly efficient differentiation into oligodendrocytes was reported first using a modified multistep EB–based protocol (Brustle *et al.*, 1999). ES-derived neural precursors were expanded with FGF2, followed by FGF2 + EGF and FGF2 + PDGF. These conditions yielded a population of A2B5<sup>+</sup> glial precursors that are capable of differentiation into both astrocytic (~36% GFAP<sup>+</sup>) and oligodendrocytic (~38% O4<sup>+</sup>) progeny on mitogen withdrawal. The 4–/4+ EB RA induction protocol has recently been optimized for the production of oligodendrocytic progeny. This study (Billon *et al.*, 2002) demonstrated efficient selection of neural progeny by both positive (Sox1–eGFP) and negative (Oct4–HSV–thymidine kinase) selection, oligodendrocytic differentiation in RA-induced EBs after expansion in FGF2, followed by dissociation and replating in serum-free medium containing FGF2 and SHH. The final step involved SHH and FGF2 withdrawal and the addition of PDGF and thyroid hormone (T3). Under these conditions, ~50% of all cells express oligodendroglial markers. Optimized conditions for oligodendrocyte differentiation using HepG2 or default

neural differentiation protocols have not yet been reported. However, stromal feeder-mediated induction, initially thought to bias toward neuronal progeny (Kawasaki *et al.*, 2000), can readily be adapted to derive oligodendrocytes at very high efficiencies and without requiring any genetic selection (Barberi *et al.*, 2003). In human ES cells, oligodendrocytic fates have been reported *in vitro* and *in vivo* (Keirstead *et al.*, 2005; Nistor *et al.*, 2005; Tabar *et al.*, 2005). The use of oligodendrocytic progeny in spinal cord injury has been proposed as one of the first clinical applications for human ES cells.

### Astrocytes

Highly efficient differentiation of ES cells into astrocytes has been reported recently using stromal feeder-mediated neural induction, followed by sequential exposure to FGF2, FGF2/EGF, EGF/CNTF, and CNTF. Over 90% of all cells expressed the astrocytic marker GFAP under these conditions (Barberi *et al.*, 2003). Significant numbers of GFAP cells were also obtained using HepG2-mediated neural differentiation (Rathjen *et al.*, 2002) or multistep EB protocols (Brustle *et al.*, 1999). Glial progenitors obtained with a multistep EB protocol were recently “transplanted” *in vitro* into hippocampal slices and revealed that full physiological maturation of ES-derived astrocytes can be achieved on interaction with an appropriate host environment (Scheffler *et al.*, 2003). Under these conditions, ES-derived astrocytes integrated seamlessly into host astrocytic networks tightly coupled via gap junctions. Human ES cells also readily give rise to astrocytic progeny (Tabar *et al.*, 2005; Zhang *et al.*, 2001).

### ES-Derived Neural Crest Progeny

ES cells provide a powerful assay to study neural crest development *in vitro*. The main strategy for deriving neural crest-like structures from ES cells is based on the exposure to BMPs following neural induction. The feasibility of this approach was demonstrated for mouse and nonhuman primate ES cells using the PA6 stromal feeder cell system (Mizuseki *et al.*, 2003). This study showed the development of both sensory as well as sympathetic neurons in a BMP dose-dependent manner. The derivation of smooth muscle cells required growth in chicken extract in combination with BMP withdrawal. No melanocytes or Schwann cells could be obtained under these conditions (Mizuseki *et al.*, 2003). Another recent study suggested efficient neural crest induction, including Schwann cell differentiation, using an EB-based multistep differentiation protocol in combination with BMP2 treatment (Gossrau *et al.*, 2003). Neural crest formation has also been reported in HepG2-mediated neural differentiation protocols on exposure to staurosporine (Rathjen *et al.*, 2002), previously reported to induce avian neural crest development (Newgreen and Minichiello, 1996). However, characterization of neural crest progeny was limited to morphological observations and expression of

Sox10, a marker expressed during neural crest development but also during glial development in the CNS. Recent studies demonstrated neural crest progeny from human ES cells (Pomp *et al.*, 2005) and the ability to yield melanocyte-like cells (Motohashi *et al.*, 2006). Future studies will be required to systematically define conditions for the derivation of all neural crest lineages *in vitro* and to validate stability and function of neural crest phenotypes *in vivo*. One particularly interesting strategy for the future might be the isolation of neural crest stem cell populations from ES cells. Such ES cell-derived neural crest stem cells could be derived at various developmental stages and of various regional identities to re-create more fully the neural crest diversity *in vitro*. The derivation of unlimited numbers of neural crest stem cells derived from mouse or human embryonic stem cells will provide an important alternative to studying neural crest biology, given the limited availability and the lack of techniques to reliably expand primary neural crest stem cells *in vitro*.

## V. APPLICATIONS IN BIOLOGY AND DISEASE

### Tissue Engineering

Stem cell biology and tissue engineering are highly complementary approaches to achieve ultimate control over cell fate, cell behavior, and *in vivo* performance. Engineering approaches have been used to influence neuronal fate specification in neural progenitor cultures using high-epitope-density nanofibers. Nearly exclusive neuronal differentiation was achieved using such nanofibers presenting the laminin epitope IKVAV at the expense of astrocytic differentiation (Silva *et al.*, 2004). Matrix conditions that influence neuronal subtype specification have also been reported during neural differentiation of mouse ES cells. In this study, laminin-based attachment matrices promoted GABAergic fates in a multistep EB-based protocol (Goetz *et al.*, 2006). Three-dimensional fibrin matrices have been used to optimize neural differentiation in the classic 4-/4+ protocols (Willerth *et al.*, 2006). The combination of 3D matrices such as poly(lactic-co-glycolic acid)/poly(L-lactic acid) polymer scaffolds with defined-growth factors promoted the growth of various tissue types from human embryonic stem cells, including neural fates (Levenberg *et al.*, 2003).

Another important application for tissue engineering in neural stem cell biology is the ability to guide axonal growth using tools such as photofabricated gelatin-based nerve conduits (Gamez *et al.*, 2004) or alginate-based capillary hydrogels (Prang *et al.*, 2006). The combination of peripheral nerve conduits, growth factors, and fibrin glue has been used successfully in animal models of spinal cord injury (Cheng *et al.*, 1996). Other engineering approaches to spinal cord injury include the use of polymer scaffold in combination with neural stem cells that appear to promote endogenous axon regeneration (Teng *et al.*, 2002). Neural stem cells

embedded in scaffolds have also been used as “biobridges” to fill cavities in the brain caused by hypoxic ischemic injury (K. I. Park *et al.*, 2002). Such implants were capable of rerouting axonal projections within the host brain, though it remains to be determined whether the induced plasticity can be sufficiently controlled to predict functional outcome. The progress in neural fate specification and ES cell biology will provide unprecedented opportunities for tissue engineering. These will be not limited to the use of engineering to enhance stem cell technologies but include the use of stem cell-derived products for engineering applications such as the development of neural prostheses, neural networks, and sophisticated neural computing.

### Disease Modeling

Embryonic stem cells offer a host of attractive features for use in developmental biology, disease modeling, and drug development. Some early examples of how ES cells could be harnessed for the study of neural disease are in the area of Parkinson’s disease, Alzheimer’s disease, and ALS. For each of these diseases, cell lines carrying specific genetic alterations associated with the disease have been generated. DJ1-mutant ES cells mimic a rare recessive form of Parkinson’s disease and faithfully reproduce failures in oxidative stress response (Martinat *et al.*, 2004). SOD1G93A-mutant ES cells can be used to study cell intrinsic versus cell non-autonomous features in ALS (Bruijn *et al.*, 2004). There are also recent reports on the neural differentiation of ES cells that exhibit the disease-causing mutant of APP knocked into the endogenous APP locus (Abe *et al.*, 2003) and mutant APP expressing neural progenitors (Millet *et al.*, 2005). Other potentially interesting applications include the use of neural stem cells to model for prion infectivity and disease progression, allowing efficient matching of disease agent and genetic background (Giri *et al.*, 2006; Milhavet *et al.*, 2006). Such pilot studies suggest that ES cells can be used to model important aspects of neurodegenerative disease and may present a uniquely suitable system to develop for pharmacological screens and high-throughput drug discovery.

### Cell Repair

One of the driving forces behind deciphering the developmental program that controls cell fate specification is the hope that such insights could be harnessed for generating specialized cells for therapy. Despite the excitement about the potential of ES cells in neural repair, there are only a few examples where such approaches have been tested in animal models of disease.

### Cell Transplantation

#### Parkinson’s Disease (PD)

One of the most widely discussed applications is the derivation of unlimited numbers of dopamine neurons from human ES cells for the treatment of Parkinson’s disease. PD

is particularly attractive for cell transplantation due to the relatively defined pathology that mainly affects midbrain dopamine neurons and the mostly unknown etiology that currently precludes causative treatment. At the onset of clinical symptoms, the majority of midbrain dopamine neurons have already died, providing further rationale for a cell-replacement approach. The first ES cell-based study that showed functional improvement in 6OHDA-lesioned rats, an animal model of Parkinson’s disease, was based on the transplantation of low numbers of largely undifferentiated mouse ES cells isolated after short-term differentiation in EB cultures (Bjorklund *et al.*, 2002). Spontaneous differentiation into large numbers of neurons with midbrain dopamine characteristics was observed. However, the clinical relevance of this approach is rather limited due to the high rate of tumor formation (>50% of the animals with surviving grafts developed teratomas). At the same time, remarkable functional improvement was obtained after transplantation of dopamine neurons derived from mouse ES cells overexpressing Nurr1 (J. H. Kim *et al.*, 2002). This study was based on a multistep EB differentiation protocol. In addition to behavioral restoration in 6OHDA-lesioned rats, this study demonstrated *in vivo* functionality via electrophysiological recordings from grafted dopamine neurons in acute brain slices obtained from the grafted animals. However, the need for genetic modification raises safety concerns that may preclude clinical translation. Functional recovery with dopamine neurons derived from naive mouse ES cells was recently reported (Barberi *et al.*, 2003). This study demonstrated functional improvement *in vivo* after grafting dopamine neurons derived from ES and nuclear transfer ES (ntES) using stromal feeder-mediated differentiation. Successful grafting of ntES-derived dopamine neurons provided a first example of therapeutic cloning in neural disease (Barberi *et al.*, 2003). Differentiation of human ES cells into midbrain dopamine neurons has been reported following a stromal feeder-based strategy of neural induction, ventral midbrain specification by combined exposure to SHH/FGF8, and terminal differentiation in the presence of various differentiation and survival factors, including ascorbic acid, BDNF, GDNF, dbcAMP, and TGFβ3 (Perrier *et al.*, 2004). A number of variations have been developed over the last few years, and alternative EB-based strategies have also emerged (Schulz *et al.*, 2004; Y. Yan *et al.*, 2005). However, unlike mouse ES-derived DA neurons, the survival of human and nonhuman primate ES-derived DA neurons has remained rather poor, with no or modest behavioral effects and with significant contamination of ES-derived forebrain precursors (Ferrari *et al.*, 2006; Martinat *et al.*, 2006; C. H. Park *et al.*, 2005; Sanchez-Pernaute *et al.*, 2005; Sonntag *et al.*, 2006; Takagi *et al.*, 2005). A recent study suggested that coculture with primary immortalized human midbrain astrocytes may significantly increase the survival of human ES cell-derived DA neurons *in vitro* and *in vivo*. However, the study found tumors in all the grafted animals, making

interpretation of behavioral data problematic and raising considerable safety concerns for this approach. However, the large numbers of surviving TH<sup>+</sup> neurons reported in this study are a first step in the development of preclinical strategies for the treatment of PD.

#### Huntington's Disease (HD)

The pathology in HD preferentially affects GABAergic medium spiny neurons, the main neuron subtype in the striatum. Similar to PD, fetal tissue transplantation trials in HD (Bachoud-Levi *et al.*, 2000; Freeman *et al.*, 2000; Gaura *et al.*, 2003) provide guidance on how to design stem cell-based approaches for HD. However, in the case of HD, the grafted cells need to project long distances from the striatum to the globus pallidus and the substantia nigra pars reticulata. ES-derived GABAergic neurons have not yet been tested in any animal model of HD, but the *in vitro* derivation of GABA neurons with forebrain characteristics has been achieved at high efficiencies (Barberi *et al.*, 2003; Watanabe *et al.*, 2005), though the proportion of medium spiny neurons among these GABA cells has not yet been determined. Another interesting avenue for stem cell research in HD is the recent derivation of human ES cells with HD mutations from embryos discarded after preimplantation diagnostics (Mateizel *et al.*, 2006). Such HD ES cell lines may provide invaluable insights into the selective vulnerability of the striatal GABAergic cell population.

#### Spinal Cord Injury and Motoneuron Disorders

Traumatic or degenerative injuries to the spinal cord are often devastating and irreversible. Cell replacement using stem cells has been touted as a potential application for stem cell research. However, the complexity of cell therapy in spinal cord injury is enormous and far from resolved. Motor neurons are one of the main cell types affected by spinal cord injuries and by various degenerative diseases, such as ALS. The efficient derivation of motoneurons from mouse ES cells has been demonstrated with both EB-based (Wichterle *et al.*, 2002) and stromal feeder protocols (Barberi *et al.*, 2003; Mizuseki *et al.*, 2003). The functionality of ES-derived neurons *in vivo* has been addressed via xenografts into the developing chick spinal cord (Miles *et al.*, 2004; Soundararajan *et al.*, 2006; Wichterle *et al.*, 2002). However, a more recent study showed that mouse ES-derived motoneurons can survive in the adult spinal cord (Harper *et al.*, 2004) and that the application of a cocktail of growth factors can partly overcome white matter inhibition and improve target innervation (Deshpande *et al.*, 2006). Despite such progress, issues related to motoneuron subtype specification, survival in the diseased spinal cord, and efficiency of axonal projections remain formidable challenges for future translation. Functional improvement in a rodent spinal cord injury model have been reported after grafting mouse ES cells differentiated using a modified 4–/4+ protocol (McDonald *et al.*, 1999). The grafted cells differentiated *in*

*vivo* into oligodendrocytes, neurons, and astrocytes and induced significant functional improvement in BBB scores as compared to sham injected animals. The mechanism by which functional improvement was obtained remains controversial (Privat *et al.*, 2000). Based on the ability for efficient differentiation into oligodendrocytes *in vivo*, it was suggested that remyelination of denuded axons might be a key factor (McDonald *et al.*, 2000). Functional improvement was also reported after grafting EB-derived cells obtained from human EG cells (Kerr *et al.*, 2003). EB-derived cell populations derived from human EG cells were implanted into the CSF of rats after virus-induced neuronopathy and motor neuron degeneration, a model of ALS. While a very small number of transplanted cells started to express markers compatible with motor neuron fate, most cells differentiated into neural progenitor or glial cells. It was concluded that the functional improvement was due to enhancing host neuron survival and function rather than to reestablishing functional connections from graft-derived motoneurons. The same hypothesis of protecting host neurons and providing myelin to surviving but denuded host axons led to the development of human ES cell-based grafting strategies using oligodendroglial precursors (Faulkner and Keirstead, 2005; Keirstead *et al.*, 2005; Nistor *et al.*, 2005).

#### Stroke

Limited information is available on the performance of ES-derived progeny in animal models of stroke. A recent study showed that grafted ES cells can survive in a rat stroke model induced by transient ischemia via occlusion of the middle cerebral artery. The goal of this study was noninvasive imaging of the grafted cells using high-resolution MRI after transfection with ultrasmall superparamagnetic iron oxide particles (Hoehn *et al.*, 2002). Transplantation of neurally differentiated progeny was reported for mouse ES cells expressing Bcl-2 (Wei *et al.*, 2005) and for primate ES-derived neural progenitors (Hayashi *et al.*, 2006; Ikeda *et al.*, 2005b), with evidence of graft-derived projections into the host brain. Cell transplantation efforts for the treatment of stroke are complicated by the multiple cell types that are affected and the variability of the affected cell populations, depending on stroke location.

#### Demyelination

There is significant evidence for the ability of primary and immortalized neural progenitor cells to achieve remyelination in a number of relevant animal models (Groves *et al.*, 1993; Windrem *et al.*, 2004; Yandava *et al.*, 1999). The capacity of mouse ES-derived progeny to remyelinate *in vivo* has been demonstrated after transplantation of highly purified ES-derived glial progenitors into the spinal cord of *md* rats (Brustle *et al.*, 1999) that lack the X-linked gene encoding myelin proteolipid protein (PLP), an animal model of Pelizaeus–Merzbacher syndrome. This study showed impressive *in vivo* differentiation results and yielded large

grafts composed of myelinating oligodendrocytes. However, the grafted cells were not able to extend the short life span of these animals, precluding detailed functional analyses. A second study demonstrated remyelination after grafting purified oligosphere cultures derived from 4–/4+ EBs into the spinal cord of *shiverer* mice or into the chemically demyelinated spinal cord (Liu *et al.*, 2000).

The recent success in generating oligodendrocytes from human ES cells with evidence of *in vivo* remyelination capacity (Nistor *et al.*, 2005) offers a new dimension toward preclinical and clinical applications.

### Endogenous Recruitment

The persistence of proliferating neural precursors in the adult SVZ and hippocampus suggests recruitment of endogenous cells as a potential alternative to cell transplantation. Endogenous recruitment offers considerable advantages, given the noninvasive nature and lack of adverse immunological, inflammatory, or vascular response. However, it appears likely that these approaches will be limited to selective brain regions. Examples include the recruitment of SVZ-type neural precursors to the striatum (Arvidsson *et al.*, 2002) and differentiation of proliferating hippocampal precursors into CA1 pyramidal neurons (Nakatomi *et al.*, 2002). Increased efficiency of striatal neuron differentiation was achieved by ectopic expression of BDNF via adenoviral vectors (Chmielnicki *et al.*, 2004) or by the stimulation of the SVZ precursor population using FGF2 or Notch activation (Androutsellis-Theotokis *et al.*, 2006). Some of the preclinical models that may benefit most from these approaches for striatal repair are stroke and Huntington's disease.

One of the most intriguing reports regarding endogenous precursor cell potential was the replacement of cortical projection neurons through presumptive recruitment of SVZ precursors (Magavi *et al.*, 2000). The results of this study suggested that the minimally invasive nature of cell ablation via retrograde uptake of a phototoxic dye may have uncov-

ered a broader differentiation potential inherent to SVZ precursors but suppressed in conventional injury models. However, the extremely low efficiency of the effect and the limited follow-up make it difficult to judge the full impact of this finding.

## VI. CONCLUSION

Embryonic stem cell–derived primary and endogenous neural stem cells provide unique tools for basic research and the development of new therapies. Embryonic stem cells offer unlimited cell numbers, full differentiation potential, and ease of introducing stable genetic modifications. Primary neural stem cells have a more limited proliferation and differentiation potential. However, for applications suitable to primary neural stem cells, they may offer a greater level of predictability and safety. Endogenous neural precursors can be harnessed without the invasive extraction of transplantation procedures, but our current understanding allows only limited control over cell fates, migration behavior, and functional integration. Beyond the role in regenerative medicine, neural stem cells, particularly ES cell–derived neural progeny, will become an essential tool for gene discovery and the study of basic development and disease. The generation reporter ES cells libraries and the establishment of cell lines with loss-of-function and gain-of-function mutations for most genes should become a reality in the near future. *In vitro* ES cell differentiation protocols will provide unlimited sources of defined neuronal and glial subtypes for pharmacological and genetic screens and for use in toxicology. However, one of the most important contributions of neural stem cell biology may be its role, as in basic biology, in unraveling the complex signals governing development from pluripotency all the way through neural specification and the formation of complex neuronal networks. Aspects of neural stem cell biology and tissue engineering will likely merge into a new, coherent discipline at the cutting edge of biology, tissue engineering, and modern medicine.

### I. INTRODUCTION

Tissue-engineered brain implants have great potential to enable future treatments of many neurological disorders for which no disease-modifying treatments are available. Proof-of-concept clinical studies of cell replacement and restorative treatments have already been made in the clinic, with mixed but encouraging results. In particular, the human fetal tissue transplantation in Parkinson's disease (PD) has paved the way for more advanced tissue-engineering concepts.

A major obstacle to developing cellular implants for a large number of patients has been the inability to grow cells with the appropriate therapeutic potential in large numbers. The discovery of expandable stem cells from both embryonic and adult sources has therefore created exciting sources of cell lines potentially applicable to a large number of patients. In combination with an increasing knowledge of developmental biology, these expandable stem cell preparations can be increasingly pushed into relevant therapeutic cells for use in tissue-engineered brain implants.

In parallel with the cell replacement approaches, restorative and neuroprotective therapies have been developed that utilize the therapeutic effects of endogenous or genetically engineered protein factors. Encapsulated cell biodelivery devices have been made that combine advanced tissue engineering with genetic engineering to deliver regenerative growth factors to the brains of patients with neurological

disorders such as PD. In combination with growth factors, artificial scaffoldings, and axonal outgrowth modulators, more sophisticated implants are being generated. In the future, implants like these are likely to restore more complex neural circuits and help a large number of patients in great medical need.

Experimental data strongly support the use of brain implants and tissue-engineering concepts in the treatment of brain disorders and promise new disease-modifying medical products for patients. Various cellular implants have already been applied in the clinic in proof-of-concept studies in Parkinson's disease (PD) (Lindvall and Björklund, 2004), Huntington's disease (HD) (Dunnett and Rosser, 2004), Alzheimer's disease (AD) (Blesch and Tuszynski, 2004), epilepsy (Björklund and Lindvall, 2000), and stroke (Savitz *et al.*, 2004). However, a cellular implant has yet to reach the market as a therapeutic product. PD has been a major target for brain implants and in this chapter is used as a disease example to illustrate the tissue-engineering concepts applied so far.

Despite the success of many drugs for PD, such as L-3,4-dihydroxyphenylalanine (L-dopa) therapy, introduced in the late 1960s, the current treatments of PD do not stop the progressive dopamine neuron dysfunction and cell death. Therefore, with time, patients on chronic L-dopa therapy develop both progressive symptoms and drug-induced side effects and require additional treatment options. In the early 1990s, surgical treatment strategies initially developed

during the 1950s, such as the ventrolateral pallidotomy for Parkinsonian rigidity, were rejuvenated because new treatment strategies were desperately needed (Speelman and Bosch, 1998). With improvements in imaging and surgical techniques, ablative procedures have yielded excellent results in selected groups of PD patients. Implantable neural stimulators that inhibit neuronal transmission in local areas by high-frequency stimulation have more recently replaced much of the ablative therapies and can yield good therapeutic results without inducing permanent lesions in the brain (Deuschl *et al.*, 2006). Despite these successful applications of neurosurgical procedures to PD, these procedures are based on the inhibition or destruction of normal neurons in attempts to compensate for the disease damage. They do not address the biology of the underlying disease itself, and, albeit successfully applied in many patients, the destruction or inhibition of normal tissue is not an optimal treatment for neurological disorders. There is therefore a need for new treatment strategies that can address the pathology more directly and offer disease-modifying effects. Fortunately, the accumulated knowledge of the pathological processes, molecular and cell biology, biomaterials, imaging, and surgical procedures now make it possible to implement disease-modifying tissue-engineering concepts in the treatment of PD and other neurological diseases.

In many untreatable neurological disorders, the progressive loss of neurons and their associated function is the primary underlying cause for the symptoms. Therefore, various cell implant strategies have been designed either to *replace* the neurons or their function or to *protect or regenerate* the function and health of the diseased neurons or a combination of both (Fig. 64.1). Clinical applications to replace the dopaminergic function in patients with PD have so far utilized primary tissues or cells. Dopaminergic neurons derived from stem cells and more sophisticated tissue-engineered implants have not yet been applied in the clinic, but rapid progress in preclinical efforts is being made in this area. In neuroprotective or restorative strategies, cellular implants secreting either endogenous or engineered growth factors or cytokines have successfully been applied in animal models and even in the clinic for amyotrophic lateral sclerosis (ALS) (Aebischer *et al.*, 1996), HD (Bloch *et al.*, 2004), and AD (Tuszynski *et al.*, 2005).

This chapter reviews some of the cell replacement and regenerative brain implants applied in the clinic and what may be developed in the future.

## II. CELL REPLACEMENT IMPLANTS

### Primary Tissue Implants

As already mentioned, oral L-dopa therapy is the main treatment for PD. L-dopa is a precursor to dopamine that passes the blood–brain barrier and is taken up mainly by the dopaminergic neurons that in turn convert L-dopa to dopamine and increase their dopamine production and

**FIG. 64.1.** Cell replacement and protective/regenerative brain implants in PD. The degeneration in PD is schematically depicted, showing an accelerated dopaminergic cell loss as seen in patients. At the time of symptoms, about 60% of the dopaminergic neurons remain and would be amenable to neuroprotective or restorative treatment with the application of protective and regenerative factors. In late-stage PD, the need for the replacement of lost dopaminergic neurons may be necessary. In future tissue-engineering strategies, a combination of cells, growth factors, and polymeric scaffoldings may be able to regenerate the dopaminergic pathways in a physiological manner and restore normal functioning. The relatively local degeneration in PD makes this disease a good initial target for brain implants, in comparison to stroke or other diseases with more unpredictable and diffuse injuries.

storage. However, with the progressive loss of dopaminergic neurons, the L-dopa therapy eventually becomes ineffective, and severe fluctuations in the ability to initiate movements occur. Because of the finding that L-dopa can increase the production of dopamine and alleviate the symptoms of PD, a reasonable therapeutic approach may be to implant dopamine- or L-dopa-secreting cells in the relevant areas of the brain (striatum).

Considering this idea, the first clinical transplantation for PD using a cellular brain implant was done at the Karolinska Hospital in Stockholm, Sweden, in the early 1980s (Backlund *et al.*, 1985). In this experimental procedure, autologous dopamine-secreting adrenal chromaffin cells were harvested from one of the adrenal glands from the patient and successfully transplanted to the striatum. The procedure was adopted very quickly by the medical community, and initial reports indicated good clinical results. However, with time, other studies showed poor survival of the cells and minimal positive clinical effects, resulting in cessation of the treatment. However, the concept of cellular brain implants had made its definite entry into the clinic, and many lessons were learned along the way.

At about the same time as the first chromaffin cell transplants were made in Stockholm, a promising cell transplantation strategy for PD was developed by Anders Björklund and coworkers at Lund University in southern Sweden (Björklund and Lindvall, 2000). They collected discarded aborted fetal tissue and dissected out the ventral mesen-

cephaion to create cell suspensions containing developing dopaminergic neurons for transplantation experiments. After several years of extensive validation of the concept in animal models, cells were transplanted to the striatum of two patients (Lindvall *et al.*, 1988). The first results were relatively unimpressive but prompted modifications to various parts of the experimental procedure, and a second pair of patients transplanted about one year later with the modified techniques fared much better (Lindvall *et al.*, 1994). These patients showed positive clinical recovery starting about four months after the procedure. Positron emission tomography (PET) data indicated that the grafts were able to survive and take up and secrete dopamine. More than 10 years out from the procedure, one of the patients showed persistent graft viability on PET scanning, and the patient was maintained on minimal L-dopa therapy (Piccini *et al.*, 1999). To date, more than 300 patients have been transplanted with fetal ventral mesencephalic tissue at different centers around the world. However, the lack of suitable donor material, the heterogeneity of the tissues and preparations, and the inability to industrialize the process have all made it difficult to establish standardized medical trials and therapy geared to a large number of patients. In fact, two controlled trials with fetal transplantation have shown only minimal efficacy, and some patients have developed movement side effects (dyskinesias) that appear related to the grafting procedure (Freed *et al.*, 2001; Olanow *et al.*, 2003). Therefore, fetal transplantation as a therapy for PD has come to a halt, and cell replacement strategies for PD are awaiting alternative cells and implants that lend themselves to a reproducible industrial process applied in well-controlled trials.

It also should be noted that clinical trials with porcine-derived ventral mesencephalic cells also failed in clinical trials (A. Pollack, 2001). With concerns regarding the transmission of animal diseases to humans (zoonosis), few if any additional clinical applications of animal-derived cellular brain implants are currently ongoing. In fact, the use of animal-derived products in the manufacture of human brain implants should be avoided to the largest degree possible, because safety and regulatory concerns should be minimized.

Despite disappointing results in the clinical application of both chromaffin and fetal-derived primary tissues from both human and pig sources, the experimental work surrounding primary tissue transplantation in PD has demonstrated several important points that will facilitate the development of tissue-engineered implants in the treatment of PD and other neurological disorders.

1. Allogeneic cells can survive over many years in the brain after a relatively brief initial immunosuppression therapy (18 months) but do not survive well without it.
2. Grafted neurons can integrate, function, and interact with the host brain in a physiological and reciprocal manner.

3. Trial designs and outcome measures have been developed that facilitate safety and efficacy measures in the clinic.
4. Surgical techniques have been developed that allow for the injection and implantation of cells and tissue-engineered products in the brain.
5. Imaging techniques have been developed to evaluate the implantation and function of the brain implants.
6. Animal models have been developed to translate and scale-up experimental brain implants for the clinic.

### Cell Line Implants

As mentioned earlier, important drawbacks using primary tissues are its limited supply, its heterogeneity, and the difficulty and prohibitive costs to implement the necessary good manufacturing principles (GMP) for harvesting, manipulation, storage, and later use. For example, fetal transplantation experiments in PD required fresh tissue from four to eight donors, resulting in procedural difficulties and poor quality control, and may help explain the poor efficacy outcomes in the aforementioned controlled trials.

Therefore, the ability to expand and store cells in cell banks is paramount to create allogeneic cell alternatives to primary tissue sources. The expansion of normal and genetically unmodified cells derived from tissue donations can give rise to expandable primary cell lines potentially useful for brain implantation with or without further manipulation. The primary cell lines normally retain a limited number of cell cycles but allow for the proliferation of enough cells to transplant hundreds to thousands of patients from a single donor. Cultured primary cells can be expanded while retaining normal geno- and phenotypes, with contact inhibition and differentiation behaviors intact. These cells are therefore relatively safe to use, and the formation of tumors or other abnormal behaviors are relatively unlikely.

Retinal pigmented epithelial (RPE) cells derived from the retinas of organ donors can make primary cell lines with limited expansion capacity and are currently in clinical trials for PD. The RPE cells secrete L-dopa and are thought to function by increasing the intrastriatal L-dopa concentration, with subsequent conversion to dopamine by residual dopaminergic nerve endings and glia. These RPE cells are grown and transplanted on gelatin microcarriers to improve survival and prevent immune rejection. A report on a clinical pilot trial was recently published and showed that these implants were well tolerated and safe (Stover *et al.*, 2005). A Phase II trial is currently ongoing and is estimated to be finished in 2008.

The RPE cells do not work in a physiological manner and do not form neurons and associated neurites, and, even though they may help patients, it is unlikely that these implants will restore function to baseline. A more versatile source of expandable primary cell lines capable of making various replacement neurons or glia are mitogen-

responsive human neural progenitor/stem cell cultures that can be isolated from various regions of aborted and adult human central nervous system (CNS) tissues and expanded for more than one year *in vitro*. These cells are often grown as *neurospheres* and can be expanded in defined and animal-free media containing growth factors (Carpenter *et al.*, 1999). These cells can form the three major phenotypes of the nervous system (neurons, astrocytes, and oligodendrocytes) *in vitro* and *in vivo* and show excellent survival, without the formation of tumors. These human neural stem cell-containing cultures have been transplanted to various regions in animals and have been shown to survive, integrate, migrate, differentiate, extend neurites, and arborize (Fricker *et al.*, 1999). Even though the cells tend to retain the markers consistent with the anatomical region from which they were isolated (Piao *et al.*, 2006), the cells can be manipulated with epigenetic and genetic factors to make specific cellular subtypes potentially useful for cell replacement implants. For a PD application, relevant nigral dopaminergic neurons need to be generated from these cells. However, so far only dopaminergic neurons with limited differentiation have been generated (Christophersen *et al.*, 2006). Reportedly, clinical applications in Batten's disease with unmanipulated human neurosphere cell lines are currently being explored (Stem-Cells, Inc., press release, 2006).

In addition to neurospheres, adherent primary cell lines of neurogenic glia have been made from both mouse and human developing neural tissues that display a glial phenotype during expansion but are capable of generating neurons during differentiating conditions (Skogh *et al.*, 2001). Similarly, so-called NS cells, expressing glia and stem cell markers, have been derived from ES cells and the developing CNS and appear to differentiate into neural phenotypes similar to those of the adherent glia and neurosphere cultures (Pollard *et al.*, 2006). The adherent cultures may have an advantage over neurospheres, from an industrial point of view, as adherent cells can be readily cloned and expanded and have been shown to retain their phenotype during expansion without differentiating into a heterogeneous mixture of progenitors. It is currently unclear if neurospheres or adherent NS cells can be made into dopaminergic neurons suitable for replacement therapy in PD.

In general, all primary cell lines derived from tissue stem cells have a large but limited expansion potential and show senescence (Ostenfeld *et al.*, 2000; Villa *et al.*, 2004). This may be due to the successive loss of immortal stem cells through the asymmetric division into progenitors (as seen in neurospheres), or, alternatively, the stem cells themselves have a limit to their proliferation. Both mouse and human ES cells defy the normal senescence of primary cells and can be expanded from a single clone indefinitely without losing pluripotentiality (Miura *et al.*, 2004). From an industrial and tissue-engineering perspective, this feature is extremely attractive because a single donation could give rise to a cell line source with the capacity to make all organs of the body in unlimited numbers. One major drawback of

ES cell-derived products, however, is that the ES cell itself cannot be implanted but needs to undergo the relevant development *in vitro* to make suitable cells for transplantation, e.g., dopaminergic neurons for PD or islet cells for diabetes mellitus. Because it is difficult to make pure cultures without retaining one or more undifferentiated ES cells, both the risk of heterogeneous cell preparations and the risk of tumorigenesis need to be overcome to develop ES cell-derived brain implants (Roy *et al.*, 2006). For neural applications, the recently described ES cell-derived NS cell may become a progenitor of choice for brain implant products because it is restricted to the neural lineage and is most likely nontumorigenic and can be expanded as a clonal cell line. It is currently unclear if the undifferentiated NS cell is immortal, like its parental ES cell, or if it displays senescence, like its neurosphere counterpart.

Cell replacement strategies using cell lines need to employ differentiation or selection methods in order to make the relevant replacement cell, e.g., dopaminergic neurons for a PD application. The generation of functioning human dopaminergic neurons *in vivo* akin to those derived from primary VM tissues has been difficult to achieve. Although neurons with the dopaminergic machinery can be made from both growth factor-expanded human neurospheres and genetically immortalized committed dopaminergic neuroblasts, it has been difficult to achieve survival and function *in vivo* (Christophersen *et al.*, 2006). Interestingly, even though ES cells would hypothetically need more steps to be differentiated into dopaminergic neurons for a PD application, relatively short-step protocols that use developmental signals involved in the rostrocaudal and ventrodorsal specification of the midbrain can push mouse ES cells into functional dopaminergic neurons in a rat model of PD (Kim *et al.*, 2002). More recent studies have also identified important transcription signals involving the *Lmx1a* and *Msx1* homeobox genes that, when overexpressed in ES cells, can yield dopaminergic neurons with markers consistent with substantia nigra neurons (Andersson *et al.*, 2006). Transplantation of these dopaminergic neurons in a rat model of PD yields excellent survival, neurite extension, and function, consistent with results from primary VM tissues. These findings may pave the way forward to make relevant "nigral" dopaminergic neurons from human ES cells and neural stem cell cultures in the not-too-distant future. However, similar to other experiments with ES cells, these cells also form tumors *in vivo* (Björklund, personal communication), and this issue needs to be worked out before clinical applications.

### III. CELL PROTECTION AND REGENERATION IMPLANTS

The use of primary tissues or cell lines in cell replacement approaches is aimed at making transplantable mimics of the cells lost in the disease process. In PD, the use of chromaffin cells, dissected developing ventral mesencepha-

lon, RPE cells, or stem cells has been aimed at replacing or augmenting the dopaminergic function. However, primary tissues, cell lines, and genetically modified cells also produce secreted factors that can influence the nearby host or transplanted cells in potentially beneficial ways. Several growth factors are endogenously made by cells, including fibroblast growth factors, transforming growth factors, and interleukins, that can have neuroprotective and regenerative effects on nearby nerve cells. Custom therapeutic cell lines can also be made by genetic engineering to secrete specific growth factors such as nerve growth factor (NGF), glial cell line-derived neurotrophic factor (GDNF), and ciliary neurotrophic factor (CNTF) that when implanted in relevant anatomical areas can affect specific neuronal populations in neuroprotective and regenerative ways (*ex vivo* gene therapy).

### Cell Implants Secreting Endogenous Factors

A carcinoma cell line derived from a human testicular teratocarcinoma isolated from a metastasis in a patient has been used in clinical applications to treat stroke (Nelson *et al.*, 2002). This immortal cell line is pluripotent and can be induced to stop dividing and to differentiate into a neuronal phenotype using retinoic acid. A preparation of this cell line was investigated in the clinic for the treatment of ischemic stroke based on animal data suggesting that the postinjury transplantation of this cell line into an infarcted area can improve recovery. The mechanisms surrounding this effect are unclear but are likely related to beneficial factors released from the cells. In a study in patients with lacunar stroke in randomized controlled Phase II trials at the University of Pittsburgh, the therapy with this cell line failed to meet the efficacy endpoints (Kondziolka *et al.*, 2005). The transplantation of a cell line derived from a human cancer has obvious risks associated with it. Importantly, the approval of this trial demonstrates that cell transplantation for severe neurological disorders is seen as a reasonable strategy by the regulatory agency, as long as safety and some efficacy can be demonstrated in animal models.

Other groups are investigating the transplantation of immortal cell lines but are using genetic engineering to immortalize cells. Advances in genetic engineering have made it possible to extend the number of doublings a primary cell line can go through by inserting various oncogenes and cell-cycle regulators. This allows for the selection, clonal expansion, and banking of a large number of cells. Besides the genetic modification, these cells retain otherwise-normal genotypic characteristics. ReNeuron, a British biotechnology company, has made immortal human neural stem cells that have shown regenerative effects in stroke models (K. Pollock *et al.*, 2006). Preparations for clinical trials are under way, and it is expected that clinical trials in stroke patients will be initiated in the near future.

Similarly, StemCells, Inc., is using growth factor-expanded human neurosphere cell lines in a strategy to treat Batten's disease, a rare neurometabolic disorder, with the

idea that the endogenous enzymes and factors made by the stem cells will have a therapeutic effect (StemCells, Inc., press release, 2006).

Last, implanted autologous mesenchymal stem cells are being studied in clinical trials for stroke (Bang *et al.*, 2005) and potentially in neurodegenerative disorders (Blondheim *et al.*, 2006).

The use of nonspecific neuroprotective and regenerative strategies based on the implantation of cells with unclear mechanisms may pose regulatory problems because the risk-benefit analyses become difficult to make. For example, even though positive results were inferred from the published trial with the human teratocarcinoma-derived cell line in stroke, the clinical data were not convincing enough to continue clinical development. In this trial, no significant adverse events or tumors were reported. But if they had occurred, a major setback for tissue-engineered brain implants could have been the result. The risk-benefit analysis is often difficult, and the predictive value and scale-up issues from the use of animal models are not straightforward. The regulatory agencies have therefore a real dilemma, and, similar to the setbacks experienced in the field of gene therapy, a push to do clinical trials with poorly characterized cell preparations and mechanisms in patients desperate for a treatment may cause significant adverse events that can create setbacks for the whole field of tissue engineering. On the other hand, a too-restrictive regulatory body may make the hurdle of bringing potentially beneficial but complex tissue-engineered products into the clinic too costly and difficult.

These regulatory issues are hard to resolve. But as experience with cell-containing implants build, it is likely that the decision making and risk-benefit analyses will improve. Some of the clinical trials using primary autologous cells, such as hematopoietic or mesenchymal stem cells derived from the bone marrow, can also bypass regulatory scrutiny and only need approval by a local ethics committee. Unfortunately, this has led to the initiation of clinical trials based on very little evidence of preclinical beneficial effects, causing potentially false hopes, personal expenses, and potentially harmful side effects to patients desperate for therapy.

### Cell Implants Secreting Engineered Factors (Ex Vivo Gene Therapy)

Because PD involves a slow and progressive degeneration of dopaminergic neurons, a protective and/or regenerative strategy could be applied. Many protein factors have been shown to protect fetal dopaminergic neurons both *in vitro* and *in vivo*, and one of the most powerful factors is glial cell line-derived neurotrophic factor (GDNF) (Lin *et al.*, 1993). This factor promotes the survival (neuroprotective effect) and neurite extension (regenerative effect) of dopaminergic neurons both *in vitro* and *in vivo*. Based on positive animal data, GDNF has been tried in humans in two separate randomized clinical trials (Lang *et al.*, 2006; Nutt

**FIG. 64.2.** Stereotactic surgery for cell replacement and EC biodelivery implants. On the right, an oblique frontal view of a cut section of the human brain shows a stereotactic injection of cells into the putamen, which is the standard method used for cell transplantation in PD. On the opposite side, the placement of a regenerative and/or protective EC biodelivery device is shown. On the left, an EC biodelivery device is shown illustrating the genetically modified human cell line attached to the polymeric matrix inside of a semipermeable hollow fiber. The cell-containing active tip is held in place by an inert tether, which is secured at the level of the skull under the skin for easy access and retrieval. The genetically modified cells housed in the tip receive nutrients from the surrounding brain and remain viable for more than a year *in vivo*. The membrane is also immunoprotective and allows for the therapeutic transgene product to be secreted into the brain interstitium.

*et al.*, 2003). The first trial used monthly intracerebroventricular bolus injections of GDNF and failed to meet both safety and efficacy endpoints. The second trial employed intraputamenal infusion of GDNF and, though safe, did not meet the efficacy endpoints. This is an unfortunate outcome for patients suffering from PD, and critics of the trial have indicated that inconsistencies in catheter design and other parameters may explain the poor results (Salvatore *et al.*, 2006).

From both the clinical and animal data, it appears necessary to deliver the GDNF in low but chronic doses to the dopaminergic nerve endings within the striatum in order to have a regenerative effect. It is currently the view of many that implantation of genetically modified cells or encapsulated cells or the use of viral vectors may be better at delivering GDNF than utilizing available pumps and catheters. Safety concerns with unregulated and unstoppable gene therapeutic approaches may favor the use of a tissue-engineered product based on an implantable and retrievable encapsulated cell biodelivery of GDNF.

It is beyond the scope of this chapter to expand on the topic of *ex vivo* and *in vivo* gene therapy, but it is important to mention that the delivery of growth factors to the brain via implants is an important cornerstone of tissue-engineering strategies for brain repair.

### Encapsulated Cell Biodelivery Implants

The implantation of naked cells has the advantage of allowing for migration, integration, and the formation of

neurites and synapses in replacement strategies. The migration and honing mechanisms that neural stem cells display in models of stroke and glioma may also be utilized to deliver regenerative or tumoricidal agents in genetically modified cells. However, naked cells cannot readily be removed; and if a potent protein factor is being delivered to the brain, the inability to stop the treatment may pose a problem if untoward effects are noted or if the regenerative treatment is needed for only a limited amount of time. A device containing encapsulated cells that secrete the factor combines the advantages of cell and gene therapy with that of the safety of a retrievable device. One of the types of encapsulated cell (EC) biodelivery devices is depicted in Fig. 64.2 and consists of a hollow-fiber membrane surrounding a core of genetically modified cells seeded on a polymer matrix that in turn is attached to a tether. These encapsulated cell implants are true tissue-engineered devices that combine genetically modified cell lines with artificial scaffolding enclosed behind an immunoprotective membrane. The polymeric membrane excludes larger molecules and cells but allows for the bidirectional passage of nutrients and transgene products. The encapsulated cells can thus be protected from immune rejection, making allogeneic or even xenogeneic transplantation possible and immunosuppressive therapy unnecessary. The host is also protected from the implanted, genetically modified cells, and the risks of gene transfer or tumor formation are greatly diminished. The tether allows for handling, implantation, and removal. These devices can be implanted intraparenchymally, intracerebroventri-

cularly, or intrathecally, depending on the application. Cellular survival and continuous production of factors have been demonstrated for at least 12 months in the brain, allowing for long-term delivery of therapeutic factors (Wahlberg, unpublished data). Encapsulated devices secreting GDNF have been studied in rodent models for PD and have shown both neuroprotective and neuroregenerative effects on dopaminergic cells (Sajadi *et al.*, 2006). Plans for clinical development with these devices in patients with PD have been announced (Michael J. Fox Foundation press release, 2004).

Recently, other investigators have published data on using encapsulated choroid plexus cells in the treatment of HD, an inherited neurodegenerative disorder (Emerich *et al.*, 2006). These cells are reportedly therapeutic because they secrete various endogenous factors that have neuroprotective and regenerative effects. The application of the choroid plexus cells in this study was made with an injectable microencapsulated-cell configuration. In this setting, the encapsulation provided immunoprotection for the porcine-derived primary choroid plexus cells. Unlike the macroencapsulation described above, these devices would not be retrievable and may be less suited for applications in which the treatment may need to be stopped.

### Controlled-Release Implants

Acellular synthetic polymeric brain implants that are able to deliver protein factors or other drugs to the CNS have also been developed (Fournier *et al.*, 2003). These systems normally release drugs by degradation- or diffusion-based mechanisms over an extended time (weeks) but cannot sustain release over a long time (months), which is possible with cellular-based systems.

Appropriately designed, polymeric controlled-release devices have several possible applications and could, for example, support the survival and integration of transplanted cells. Furthermore, a polymeric system can support the sequential release of growth factors that may be necessary to fully support the stepwise differentiation of immature cells. This concept could become applicable to neural stem cells, which may lack important embryonic developmental signals in the adult brain (Wahlberg, 1997).

## IV. COMBINED REPLACEMENT AND REGENERATION IMPLANTS

From a tissue-engineering point of view, the future goal is to make replacement organs for the body that can take over the function of a failed organ or structure in an anatomically and physiologically correct manner. And even though it would be difficult if not impossible to make entirely new brains, it should become possible not only to replace cells but also to make new axonal pathways and restore the correct connections.

The transplantation of fetal dopaminergic cells to the striatum is called *heterotopic transplantation*. This means

that the dopaminergic cells are transplanted into an anatomical region different from their normal location, which is the substantia nigra (SN). The heterotopic implantation of dopaminergic neurons may result in the loss of important normal innervation and feedback loops. Many transplants for PD may thus work only as simple cellular pumps that increase the striatal dopamine levels. Although simplicity is desired, an ultimate strategy to treat PD could be to transplant the dopaminergic neurons to their anatomically correct position (homotopic), regenerate the nigrostriatal axonal pathway, and induce terminal sprouting and innervation of the striatal target neurons. This would regenerate the appropriate connections and represent a more physiologic strategy.

An initial approach may be to provide survival factors to the implanted cells. Even in the most optimal VM grafts applied heterotopically in PD, the total fraction of surviving dopaminergic neurons was only about 10–20% (Brundin and Björklund, 1987). This required a large number of donors (four to eight) to ensure enough surviving cells for a clinical effect. The combination of VM grafts with the neuroprotective and regenerative effect of GDNF is therefore a logical idea. Experimental data indeed show that the application of GDNF delivered by encapsulated cells in combination with either rat or human VM grafts increase the survival, neurite extension, and innervation of the striatum in a rat model of PD (Ahn *et al.*, 2005; Sautter *et al.*, 1998). Similarly, it would be expected that GDNF would have survival and regenerative effects on dopaminergic cells derived from ES or other stem cells when placed *in vivo*. A combined approach, with dopaminergic grafts and encapsulated cell implants secreting GDNF, may therefore be contemplated in future transplantation studies in PD.

A large challenge for tissue-engineering approaches in the treatment of neurological disorders is the regeneration of axonal pathways. Axons between the cell bodies and their targets often extend for several centimeters in the brain and close to one meter between the brain and the lumbar spinal cord neurons in an adult. Compared to the relatively short distances that the axons had to grow during development, the regeneration in the adult may pose a particular challenge. Fortunately, science has made progress in this area, and what was thought impossible only a few years ago now seems more feasible. Several molecules are now known to promote and to guide axonal outgrowth. As mentioned, GDNF is a strong promoter of axonal outgrowth of dopaminergic neurons. In addition, certain extracellular matrix (ECM) proteins, such as laminin, can guide axonal outgrowth (Zhou and Azmitia, 1988), and extensive nigrostriatal reconstruction has been accomplished using bridges of striatal tissues in combination with fetal mesencephalic grafts placed in the substantia nigra (Dunnett *et al.*, 1989). The finding that the central myelin and glial scars are inhibitory to axonal outgrowth has led to the identification of various inhibitory molecules that can be manipulated in

various ways with inhibitors and enzymes (Liu *et al.*, 2006). From a tissue-engineering point of view, the combination of replacement cells with regeneration channels or scaffolds capable of releasing survival- and neurite-promoting factors and coated with molecules that facilitate axonal outgrowth may thus become a future reality. Using nanotechnology, synthetic bridges can be made that promote extensive fiber regeneration and functional restoration (Ellis-Behnke *et al.*, 2006).

Even though mounting data show that axonal bridges can improve axonal growth in animal models, these methods have not been applied to humans. As the cellular building blocks become better refined, it is likely that more “true” tissue-engineered brain implants will enter the clinic. These types of implants could have great potential use for regeneration in many areas of the CNS, particularly the spinal cord.

## V. DISEASE TARGETS FOR BRAIN IMPLANTS

As mentioned, PD has been a major target for cellular brain implants. However, many other neurological disorders should become amenable to tissue-engineered implants.

In Huntington’s disease (HD), several neuronal populations slowly degenerate and cause the clinical signs of choreiform movements and progressive dementia. HD is inherited as an autosomal dominant disease, and the responsible mutation has been located on chromosome 4. Carriers of the disease can therefore be screened for and identified before the onset of symptoms. This makes a neuroprotective strategy for HD an attractive possibility, where the delivery of neurotrophic factors could prolong the symptom-free interval. One such factor is ciliary neurotrophic factor (CNTF), which protects striatal neurons in both rodent and nonhuman primate models of HD (Mittoux *et al.*, 2000). Considering these results, a small clinical proof-of-concept trial using an intracerebroventricularly placed encapsulated-cell device secreting CNTF was completed (Bloch *et al.*, 2004). The study indicated that the placement was safe and would warrant additional trials. However, data also suggested that improved devices and an intrastriatal implantation approach may improve the efficacy. This approach may be taken in future trials.

Cell replacement strategies have also been tried in HD (Dunnett and Rosser, 2004). Primary fetal striatal tissue transplantation for HD has been performed at a handful of centers in the world. Long-term follow-up has described mild improvements in some of the implanted patients (Bachoud-Levi *et al.*, 2006). Because the number of implanted patients is few, it is currently difficult to draw any major conclusions regarding the clinical efficacy of transplantation for HD. One possible advantage over PD is that

the transplantation for HD involves homotopic implantation, which, at least theoretically, should allow for the differentiation of the fetal tissue using normal environmental cues. However, in HD, multiple sets of neuronal populations degenerate, including both cortical and striatal neurons. The homotopic transplantation for HD may thus require more extensive regeneration of axonal pathways than in PD.

Other diseases that could be amenable to the implantation of cells within the brain are the myelin disorders. Animal experiments have shown the ability of various neural tissues, precursors, and stem cells to remyelinate areas of demyelination (Rice *et al.*, 2004).

One substitute for oligodendrocytes (the myelinating cells of the CNS) may be to transplant growth factor-expanded Schwann cells [the myelinating cell of the peripheral nervous system (PNS)]. This is based on the fact that patients with CNS myelin disorders do not display demyelination of the PNS. In fact, remyelination of central axons may occur spontaneously by ingrowth of Schwann cells from the periphery. An intriguing therapeutic possibility therefore is to grow Schwann cells from a nerve biopsy and to expand these cells in culture. In turn, these cells could be transplanted into demyelinated areas in the same patient. Physiologically, this may not be the best strategy, for Schwann cells myelinate only single axons, whereas an oligodendrocyte myelinates multiple axons. However, animal data indicate that, for a limited volume, Schwann cells can remyelinate and restore function to central demyelinated areas. Based on animal data, a small clinical study was performed. Reportedly, the Schwann cell transplants did not survive, but the procedure appears to be safe (Stangel and Hartung, 2002). It is currently unclear if new trials with Schwann cells are to be expected.

One of the most common neurological disorders is epilepsy, which affects about 1–2% of the population. Epilepsy is characterized by recurrent abnormal electrical discharges in the brain, affecting subparts of the brain or generalizing to deeper parts in the brain and resulting in unconsciousness. A subgroup of these patients has temporal lobe epilepsy, which is generated by a loss of neurons and an imbalance of inhibitory and excitatory neurotransmitters in the hippocampal formation. In medically intractable cases, this disease can sometimes be treated surgically with the removal of the medial hippocampus and the abnormal area. This procedure eliminates or reduces the frequency of seizures in selected patients but involves a major surgical procedure and the ablation of normal tissue. A less invasive procedure may be to implant inhibitory cells in the seizure focus, which would raise the seizure threshold (Björklund and Lindvall, 2000). This idea is supported by animal experimentation data that indicate that locus coeruleus grafts and the local delivery of inhibitory substances such as GABA and Galanin can increase the seizure threshold and treat established seizures.

Other disease indications that may benefit from brain implant strategies include stroke, brain injury from trauma, AD, and rare disorders such as cerebellar degeneration and inherited metabolic disorders. Besides the brain, the spinal cord and retina are potential targets for similar approaches.

## VI. SURGICAL CONSIDERATIONS

The surgical implantation of most brain implants involves the use of stereotactic techniques. The stereotactic method (stereotaxis) in brain surgery was established in the beginning of the 21st century and is now well established in neurosurgical practice (Speelman and Bosch, 1998). It involves attaching a rigid frame (stereotactic frame) to the skull, followed by imaging, such as MRI. Attached markers (fiducials) create a three-dimensional coordinate system in which any point in the brain can be defined and related to the frame with high precision. In the operating room, the markers used during imaging are replaced with holders that guide the instruments. It is a relatively simple and low-risk neurosurgical procedure often done under local anesthesia and mild sedation. The procedure is therefore safe and relatively painless. The patients are usually discharged from the hospital after an overnight observation.

## VII. CONCLUSIONS

In this chapter, various brain implants have been described that may have the potential to treat PD and other neurological disorders using tissue-engineering strategies. Most of the clinical applications to date involve the transplantation of primary cell suspensions, such as those derived from fetal tissue. The use of manipulated adult and embryonic stem cells have shown great promise in animal models, but embryonic stem cell–derived replacement cells carry risks of tumor formation. Adult neural stem cells do not tend to form tumors *in vivo*. However, these cell lines have been lacking the necessary phenotypes for clear applications in indications such as PD. Applications using growth factor support, genetic engineering, scaffolds, extracellular matrices, and encapsulation have all been able to improve survival and function of brain implants in experimental settings. Rapid development toward clinical applications is ongoing, and it is expected that cell replacement and restorative treatments using tissue-engineered brain implants will have a great impact on neurological disorders in the relatively near future. The ultimate implants are yet to be developed and may combine stem cells, genetically modified cells, controlled-delivery devices, axonal bridges, scaffolds, and encapsulated cells.

### I. INTRODUCTION

Spinal cord injury is a major medical problem because there currently is no way to repair the central nervous system and restore function. In this chapter, we focus on embryonic stem cells as an important research tool and potential therapy. We quickly review the epidemiology, functional anatomy, and pathophysiology of spinal cord injury and then discuss spontaneous regeneration and current limitations on repair. We also summarize features of spinal cord development that might guide restoration strategies. We then review studies that have utilized embryonic stem cells in spinal cord repair. We conclude that progress has been good, that knowledge is still too limited, and that harnessing the potential of embryonic stem cells will be important for solving the problem of spinal cord injury.

### II. THE PROBLEM

Nearly 12,000 people in the United States suffer a traumatic spinal cord injury (SCI) every year, and about a quarter of a million Americans are living with this devastating condition (National Spinal Cord Injury Database, 2001). There are also four to five times as many spinal cord injuries caused by medical conditions, such as multiple sclerosis, a common disorder that destroys the myelin insulation on nerves in the cervical spinal cord. Other medical causes

include amyotrophic lateral sclerosis (ALS; Lou Gehrig's disease), polio and postpolio syndrome, human T-lymphotropic virus type 1 (HTLV-1), human immunodeficiency virus type 1 (HIV-1), metabolic deficits such as of vitamin B-12, as well as causes of myelopathy, such as stenosis and disc herniation (McDonald and Sadowsky, 2002). The worldwide incidence of traumatic and nontraumatic SCI is greater per capita than in the United States.

The consequences of SCI depend on the level at which the cord is damaged. Generally, injuries in the neck produce tetraplegia, with loss of bowel and bladder function, whereas lesions in the thoracic or lumbar area may cause paraplegia, also with bowel and bladder dysfunction. In its severest form, SCI causes complete paralysis and loss of sensation throughout the body, inability to control bowel and bladder function, trouble controlling autonomic functions such as blood pressure, and inability to breathe or cough. The long-term disability from SCI results not only from the initial loss of function but also from the complications that accumulate. Up to 30% of individuals with SCI are hospitalized every year for complications (McKinley *et al.*, 1999), such as severe spasticity, infections (lung, skin, bowel, bone, urinary tract), osteoporosis and pathologic bone fractures, autonomic dysreflexia, and heterotopic ossification (McDonald and Sadowsky, 2002; Sjolund, 2002). Another major long-term

**FIG. 65.1.** Organization of the spinal cord. A segment of cord reveals the butterfly-shaped gray matter at the core and an outer ring of white matter. The main components of the gray matter are neuronal cell bodies and glial cells and blood vessels. The white matter also contains astrocytes and blood vessels, but it consists mostly of axons and oligodendrocytes (glial cells that wrap axons in white, insulated myelin). Axonal tracts that ascend in the cord, such as the one shown in red, convey sensory messages received from the body; the descending tracts (blue) carry motor commands to muscles. Reproduced with permission of Alexander and Turner Studio, FL. © 2002 Edmond Alexander.

complication is muscle wasting. This results from disuse and the absence of nerve impulses, which are critical for maintaining junctions between nerves and muscles (Auld and Robitaille, 2003; Rossi *et al.*, 2003). Therefore, patients who maintain their body in the best condition for nervous system repair will benefit most from future therapeutic strategies.

### III. SPINAL CORD ORGANIZATION

Unlike the brain, the spinal cord has its white matter (nerve axons) on the outside and gray matter (cell bodies) on the inside (Fig. 65.1). The gray matter houses neurons that project to their level of the periphery to control movement and receive sensory signals. The white matter carries axonal connections to and from the brain, and half of all those axons are myelinated. In general, the spinal cord has much less potential for regeneration than the peripheral nervous system. Moreover, most traumatic SCIs also injure the incoming and outgoing (*afferent* and *efferent*) peripheral nerves at the injury level. In most cases, however, the caudal cord remains intact beginning several segments below the injury level. Circuitry in those segments can produce reflexes by activating a ventral motor neuron to produce muscle contraction when it receives a sensory stimulus from the periphery of the body (Fig. 65.1).

The distal spinal cord also contains groups of nerve cells that generate the patterns of activity needed for walking and running. Finally, there are central pattern generators, which

govern particular motor functions in the periphery that are quite complex in nature and well controlled. Interested readers are referred to recent monographs on this subject (Burke, 2001; Dietz, 1995; Barbeau *et al.*, 1999). Because the upper spinal cord plays only a limited role in controlling these pattern generators, people with injury to the cervical spine can walk or ride a stationary bicycle if their muscles are stimulated appropriately. The existence of additional pattern generators has also been predicted. For example, the phrenic nucleus, housed at C3 through C5 in the upper neck, appears to generate the pattern of movements needed for respiration. Unfortunately, this part of the spine is a common site of traumatic injury.

### IV. INJURY

Traumatic injury occurs when broken fragments of bone and ligament impinge on the soft spinal cord, which is no wider than the thumb. The cord responds by swelling until it encounters resistance from the bony canal of the spinal column. The swelling that compounds the initial injury reduces venous blood flow, causing a secondary venous infarct in the central part of the cord. This initiates a cascade of events that injures neighboring tissue. During this secondary phase, which occurs in the first 24 hours after the primary phase, cells die by excitotoxic necrosis (caused by release of harmful concentrations of chemicals from other cells) as well as by apoptosis (cell suicide), causing the initial injury site to enlarge rapidly into a hole in the middle

**FIG. 65.2.** Evolution of primary to secondary spinal cord injury. Following the initial trauma, the injury site enlarges rapidly as a consequence of secondary injury, particularly over the first 24 hours.

of the spinal cord (Fig. 65.2). Because a donutlike rim of viable tissue usually remains at the level of injury, SCI preferentially affects gray matter.

A second wave of very delayed cell death occurs during the weeks after an SCI (Crowe *et al.*, 1997). It removes mostly oligodendrocytes (the cells that wrap nerve axons in a fatty layer of myelin) from adjacent white matter tracts. Since each oligodendrocyte myelinates 10–40 different axons, loss of one oligodendrocyte leads to exponential loss of myelin. As a result, nerve axons cease to function because they cannot conduct electrical impulses when this insulating sheath is lost. This progressive phase of secondary injury is a good target for potential therapies, such as neuroprotective stem cell transplantation.

The problem does not stop with the secondary wave of cell death, however. An injured, underactive nervous system may be unable to adequately replace cells, particularly housekeeping cells called *glial cells*, which normally turn over. Therefore, individuals with SCI may experience a slow, progressive loss of neurological function over very long periods in addition to complications from their initial injury. It is important to consider this potential for further loss of function when designing therapeutic regimens.

## V. SPONTANEOUS REGENERATION

Not long ago, the adult nervous system was believed to have no capacity for repair or regeneration. Now a growing body of evidence indicates that the capacity for spontaneous regeneration may be much greater than previously perceived. Data obtained since the 1960s have demonstrated that new cells are added to the nervous system continually; these cells include neurons in at least two brain regions, the hippocampus and the olfactory bulb (Eriksson *et al.*, 1998; Winner *et al.*, 2002). Moreover, glial cells are frequently born and are capable of regeneration (Herndon *et al.*, 1977; Ludwin, 1984). Recent work has shown that severed or intact axons can sprout even long after injury (Weidner *et al.*, 2001).

Nonetheless, our ability to maximize spontaneous regeneration is currently limited. The recent detection of endogenous stem cells within the spinal cord raises hope

that such cells can be harnessed to repair the damaged spinal system. Although the birth of new neurons from these progenitors has never been demonstrated within the spinal cord (Horner *et al.*, 2000), new glial cells, including oligodendrocytes and astrocytes, are continually being added. In fact, injury stimulates cell birth. Our laboratory recently showed that nearly 2 million cells are born in the spinal cord each day, though most eventually die (Becker *et al.*, 2003). Collectively, these data suggest that cell turnover does occur in the nervous system, albeit much more slowly than in other organs of the body. Moreover, we recently showed that patterned neural activity, generated by repetitive tasks such as cycling, can stimulate cell birth, suggesting that behavioral modification could be important for maximizing cord regeneration and functional recovery (Becker *et al.*, 2003).

## VI. CURRENT LIMITATIONS AND APPROACHES TO REPAIR AND REDEFINING GOALS

Although some limited spontaneous regeneration is known to occur (Tuszynski *et al.*, 2002; Prewitt *et al.*, 1997), dramatic self-repair of the nervous system does not take place. A growing body of evidence suggests that factors in the nervous system actively inhibit regeneration. Such factors include inhibitory proteins in the cord, which guide regrowing connections, and scar tissue, which contains chondroitin sulfate and other proteoglycans (Morgenstern *et al.*, 2002). Reduced production of growth factors that stimulate regrowth also limits regeneration.

Figure 65.3 and 65.15 outline the general strategies for repairing the damaged spinal cord. Note that a complete cure of nervous system injury is not practical or required. Partial repair translates into proportionally greater recovery of function. For example, only about 10% of the functional connections are required to support locomotion in cats (Blight, 1983), and humans missing more than half the gray matter in the cervical spinal cord can still walk and run fairly normally.

One repair strategy is to transplant stem cells or other biomaterials to fill the cyst that forms at the eye of the injury. This cyst acts as a physical barrier to the growth of anatomically intact axons in the surrounding donut of white matter. The lost cells include segmental motor neurons, sensory neurons, oligodendrocytes, and astrocytes. Although it is possible for endogenous cells to give birth to new oligodendrocytes and astrocytes, this response is limited; moreover, it has not so far been possible to obtain new neurons in the spinal cord from endogenous cells (Horner *et al.*, 2000).

As well as filling in the cyst, it may be necessary to repair axons that no longer function properly because they have lost their myelin or have been inappropriately myelinated. Several approaches have been used to overcome this problem, which can manifest itself as a segmental

**FIG. 65.3.** Common strategies toward regeneration of the damaged spinal cord. (1) *Prevention of progression of secondary injury:* Necrotic and apoptotic cell death would be prevented by antiexcitotoxic drugs and antiapoptotic treatments. (2) *Compensation for demyelination:* Chemicals that prevent conduction block in demyelinated areas and agents that encourage surviving oligodendrocytes to remyelinate axons would be provided. Lost oligodendrocytes would be replenished. (3) *Removal of inhibition:* Agents that block the actions of natural inhibitors of regeneration or drugs that down-regulate expression of inhibitory proteins would be provided. (4) *Promotion of axonal regeneration:* Growth factors that promote regeneration (sprouting) of new axons would be provided. (5) *Direction of axons to proper targets:* Guidance molecules would be provided or their expression would be increased in host cells. (6) *Creation of bridges:* Bridges would be implanted into the cyst to provide directional scaffolding that encouraged axonal growth. (7) *Replacement of lost cells:* Cells capable of generating all cell types (progenitor cells or embryonic stem cells) would be implanted. Substances that induce undifferentiated cells to replace dead cells would be provided. Also, cells that had been genetically engineered to deliver regenerative molecules would be transplanted. Reproduced with permission of Alexander and Turner Studio, FL. © 2002 Edmond Alexander.

conduction block. For example, potassium channels on dysfunctional axons can be blocked pharmacologically, and preexisting or transplanted oligodendrocytes and their progenitors can be encouraged to make new myelin (Nashmi and Fehlings, 2001; Novikova *et al.*, 2002).

Another strategy is to remove or mask the effects of proteins in the glial scar around the cyst that actively inhibit the regrowth of new connections (Tatagiba *et al.*, 1997). Antibodies that block the inhibitory effects of these proteins promote sprouting (Tatagiba *et al.*, 1997). Alternatively, cells might be delivered to the cyst to digest inhibitory proteins in the scar; or the initial expression of such proteins might be inhibited. Moreover, certain growth factors promote the self-repair of physically broken connections. These factors can be provided exogenously or by transplanting genetically altered cells that release them (Bregman *et al.*, 2002; Murray *et al.*, 2002; Tuszynski *et al.*, 2002).

It is important to understand the feasibility of various repair strategies and to redefine appropriate goals of repair. If one ranks the foregoing strategies in terms of likely success (McDonald and Sadowsky, 2002), it becomes clear that it will be very difficult to persuade axons to regrow across a lesion, extend all the way down the spinal cord, and make connections with the appropriate target cells. Remyelination seems much more feasible because it occurs continually at a steady rate in the damaged spinal cord. It is important to investigate all possible strategies, however, because some will materialize sooner and some later. Most importantly, we must understand that multiple strategies delivered over time will be more important than the elusive magic bullet.

When defining appropriate goals for therapy, improving patients' quality of life must surely rank first. To this end, strategies that limit complications are important. Moreover, individuals with SCI often value small gains in function more highly than larger gains, such as walking. Thus, the top goal for most patients is recovery of bowel, bladder, or sexual function. Distant seconds include recovery of respiratory function for those whose respiration is impaired and use of a single hand for those without hand function (McDonald and Sadowsky, 2002). Paradoxically, most animal models focus on recovering the ability to walk. This is both the least appropriate goal and the most difficult.

## VII. SPINAL CORD DEVELOPMENT

To understand spinal cord regeneration, it is necessary to understand spinal cord development. In humans, oligodendrocytes are found in cultures of fetal spinal cord at 7 and 12 weeks of gestation (Dickson *et al.*, 1985; Satoh and Kim, 1994). Myelination begins at 10–11 weeks of gestation (Gamble, 1969; Weidenheim *et al.*, 1992) and continues throughout the second year of life (Benes *et al.*, 1994; Puduslo and Jang, 1984). Signals derived from axons regulate the growth of progenitor cells and the survival of oligodendrocytes (Barres and Raff, 1996). For example, sonic hedgehog (SHH), a protein synthesized by notocord and floor plate cells, induces the differentiation of motor neurons in the ventral cord (Roelink *et al.*, 1995), and SHH signaling induces oligodendrocyte precursors (OP) to emerge in the embryonic spinal cord (Hajihosseini *et al.*, 1996). Platelet-derived growth factor (PDGF) is a potent regulator of OP migration and proliferation, while insulinlike growth factor (IGF-1) acts on both neurons and oligodendrocytes. Other locally synthesized growth factors appear to control the balance between OP proliferation and differentiation (Dubois-Dalcq and Murray, 2000).

Many different neuronal phenotypes arise from various progenitor pools during CNS development, but most of the pathways are poorly understood. One of the best described is the generation of spinal motor neurons (Jessell, 2000), which involves several steps. Through signaling pathways that enable cells to respond to external cues (pathways involving bone morphogenetic protein [BMP], fibroblast

growth factor [FGF], and Wnt), ectodermal cells obtain a rostral neural character (Munoz-Sanjuan and Brivanlou, 2002). In response to caudalizing signals, such as retinoic acid (RA), these progenitors acquire a spinal positional identity (Durstion *et al.*, 1998). Through the ventralizing action of SHH, spinal progenitor cells gain their motor neuron phenotype (Briscoe and Ericson, 2001).

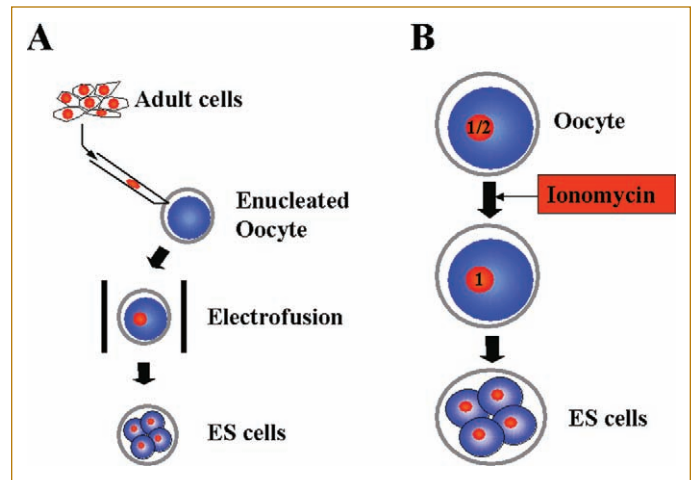

These findings raise the question of whether embryonic stem (ES) cells can be directed along specific pathways to produce specific neural cell populations for CNS repair. In fact, very encouraging steps have already been taken. Early reports revealed the possibility of generating cells with motor neuron characteristics from ES cells (Renoncourt *et al.*, 1998). Later, Wichterle and colleagues (2002) demonstrated that signaling factors operating along the rostrocaudal and dorsoventral axes of the neural tube to specify motor neuron fate *in vivo* could be harnessed *in vitro* to direct the differentiation of mouse ES cells into functional motor neurons.

## VIII. EMBRYONIC STEM CELLS

ES cells have unique features that are important for spinal cord repair. They represent every cell type in the body and are the earliest stem cells capable of replicating indefinitely without aging, and their DNA can be modified easily, even in single cells. They also fulfill two criteria that are essential for nervous system repair through transplantation: (1) They normally belong in the spinal cord; and (2) they contain the recipient's own DNA, obviating the need for immunosuppression, which cannot be used in spinal cord patients because of the increased incidence of infections.

Several methods are available for obtaining ES cells. The most common is *in vitro* fertilization, which requires a fertilized egg and therefore produces cells that differ genetically from the host. A second strategy involves somatic nuclear transfer, which takes a nucleus from a somatic cell, such as a skin cell, and transfers it to a fertilized egg whose nucleus has been removed (Fig. 65.4A) (Sotomaru *et al.*, 1999). The subsequent ES cells therefore contain only the genetic material of the recipient. Another possibility for women is parthenogenesis (Kaufman *et al.*, 1983), which tricks an egg into thinking it is fertilized, allowing it to begin duplicating its DNA (Fig. 65.4B). Although this process is unable to create a viable embryo (because factors derived from sperm are necessary for preimplantation), it can produce normal cells.

Many studies of spinal cord repair have involved differentiated cells. The earliest studies used peripheral nerve grafts to demonstrate that the nervous system has the capacity to regenerate but that the environment in the CNS is not permissive (Aguayo *et al.*, 1981). Substantial progress has been made with transplantation of peripheral nervous system cells and non-nervous system cells, including genetically engineered fibroblasts, bone marrow cells, glial cells,

**FIG. 65.4.** ES cells can be made by *in vitro* fertilization and two additional methods: **(A)** *Somatic nuclear transfer*: Donor cells are placed under the zona pelucida into the perivitelline space of enucleated oocytes. The cell nucleus is introduced into the cytoplasm by electrofusion, which also activates the oocyte. It can then be grown to the blastocyst stage to harvest the ES cells. **(B)** *Parthenogenic activation*: For activation, oocytes are briefly exposed to a calcium ionophore such as ionomycin. The resulting cell can mature for ES cell harvest.

neurons, and mixtures of glia and neurons (Bunge, 2000; Murray *et al.*, 2002; Hains *et al.*, 2003; Jiang *et al.*, 2003; Akiyama *et al.*, 2002). In general, fetal sources of cells have been the most successful because derivatives of postnatal and adult cells are less able to withstand neural transplantation. One recent exception has been neural stem cells derived from the adult CNS (Cao *et al.*, 2002a).

Another very active area of investigation is transdifferentiation (Kennea and Mehmet, 2002): isolating cells from organs other than the nervous system and transforming them into neural progenitor cells. Although initial progress suggested that this strategy might work with many types of tissue, the problem of cell-to-cell fusion may have dampened enthusiasm for this approach (Liu and Rao, 2003). Suffice it to say that transdifferentiation has not yet produced cells suitable for transplantation, although clearly the potential exists.

### Embryonic Stem Cells and the Neural Lineage

Several protocols are available for converting ES cells into neural lineage cells. However, protocols for mouse and human cells differ because the constraints of the human ES cell system have not yet been clearly defined (Fig. 65.5). Differentiating murine ES cells traditionally begins with floating spheres called *embryoid bodies*. These bodies are akin to the neural spheres of stem cells obtained from the adult CNS. Retinoic acid is a key induction agent for producing neural progenitors from mouse ES cells (Gottlieb and Huettner, 1999). Neural cells resembling anatomically

**FIG. 65.5.** (A–C) Undifferentiated mouse ES cells dividing in a culture dish. (A, C) Immunofluorescence images demonstrate anti-B-tubulin (green) and anti-DNA (Hoechst; red). The phase image (B) of the identical field (C) is shown in Panel B. (D) Undifferentiated human ES cells. (E) Embryoid bodies derived from human ES cells. Immunofluorescence (green), Hoechst 33342 (blue). Scale bar D–E = 100  $\mu$ m.

normal neurons, astrocytes, and oligodendrocytes from the CNS can easily be derived from mouse ES cells using these protocols (Fig. 65.6).

### Embryonic Stem Cell Transplantation

Use of ES cells for neural transplantation is in its infancy, and only a very limited amount of work has been completed with the spinal cord. These early studies have relied on transplantation during the embryonic (Wichterle *et al.*, 2002), postnatal (Brustle *et al.*, 1999; McKay, 1997), and adult (McDonald *et al.*, 1999; Liu *et al.*, 2000; Brustle *et al.*, 1999) periods in the normal or injured spinal cord. Overall, they demonstrate that ES cells have a remarkable ability to integrate into the injured region of the cord and differentiate appropriately.

A recent study by Thomas Jessell and colleagues provides exceptional evidence that ES cells can participate in the normal development of spinal cord cells, including motor neurons (Wichterle *et al.*, 2002). It demonstrated that developmentally relevant signaling factors can induce mouse ES cells to differentiate into spinal progenitor cells and then motor neurons through the normal developmental pathway (Fig. 65.7). Thus, the signals that promote the

differentiation of neural stem cells *in vivo* are also effective when applied to ES cells. This group further demonstrated that motor neurons derived from ES cells can populate the embryonic spinal cord, extend axons, and form synapses with target muscles (Fig. 65.8). Therefore, they not only participate in normal development but also grow appropriately when transplanted into the embryonic spinal cord, targeting muscle. Thus, inductive signals in normal pathways of neurogenesis can direct ES cells to form specific classes of CNS neurons.

Oliver Brustle, Ian Duncan, and Ron McKay were the first to transplant progenitors derived from ES cells into the adult and embryonic spinal cord (Brustle *et al.*, 1999). They demonstrated that ES cells that are transplanted into brain and spinal cord of normal adult animals can differentiate into oligodendrocytes that can myelinate axons. They generated oligodendrocyte precursors efficiently by first supplementing cultures of ES cells with fibroblast growth factor (BFGF) and epidermal growth factor and later including platelet-derived growth factor (PDGF). About 38% of the cells in the resulting cultures were oligodendrocytes. To investigate whether these oligodendrocytes could myelinate *in vivo*, cells grown in the presence of BFGF and PDGF

**FIG. 65.6.** ES cells differentiate into the principal types of neural cells. **(A)** Type I and **(B)** type II astrocytes (anti-GFAP). **(C)** Oligodendrocytes (anti-O1). **(D)** Neurons (anti- $\beta$  tubulin). Scale bar = 10  $\mu$ m. From Becker *et al.* (2003). Reproduced with permission.

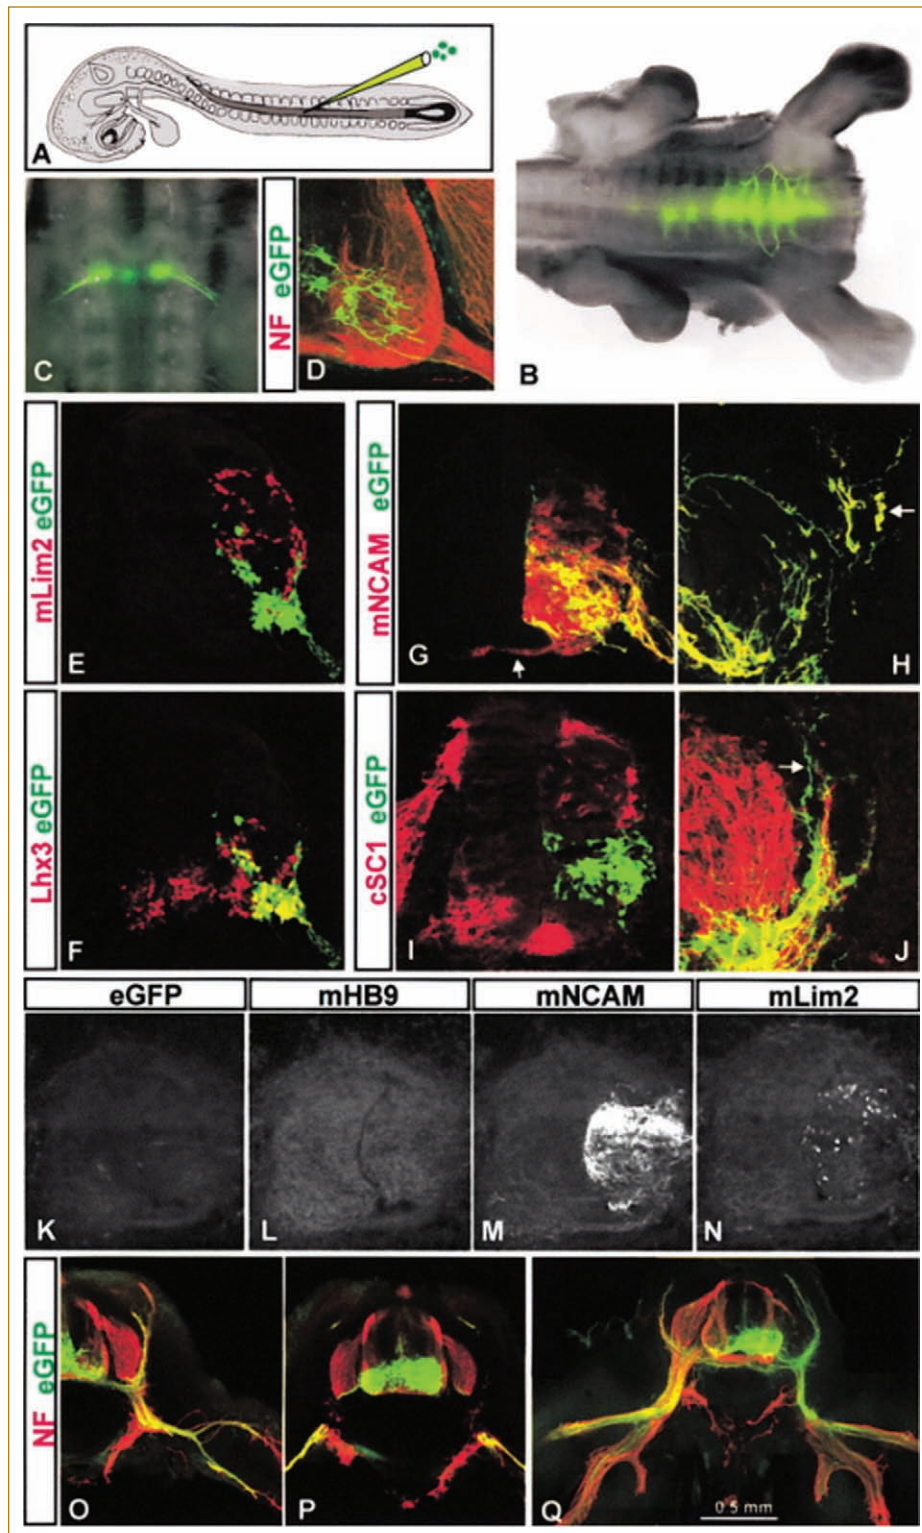

were injected into the spinal cord of one-week-old myelin-deficient rats, a model for a human myelin disorder. Two weeks after transplantation, numerous myelin sheaths were detected in six of the nine affected rats. The original 100,000 cells had migrated widely, and they made myelin with appropriate ultrastructure. Therefore, glial precursors derived from ES cells and transplanted into the neonatal rat spinal cord migrated over several millimeters and differentiated into myelinating oligodendrocytes and astrocytes.

This group also transplanted precursors derived from ES cells into the cerebral ventricles of developing rodents (embryonic day 17) (Brustle *et al.*, 1999). Three weeks later, proteolipid protein (PLP)-positive myelin sheaths were evident in a variety of brain regions. The cells' exogenous origin was confirmed by *in situ* hybridization with a probe to mouse satellite DNA. Importantly, there was no observable evidence of abnormal cellular differentiation or tumor formation.

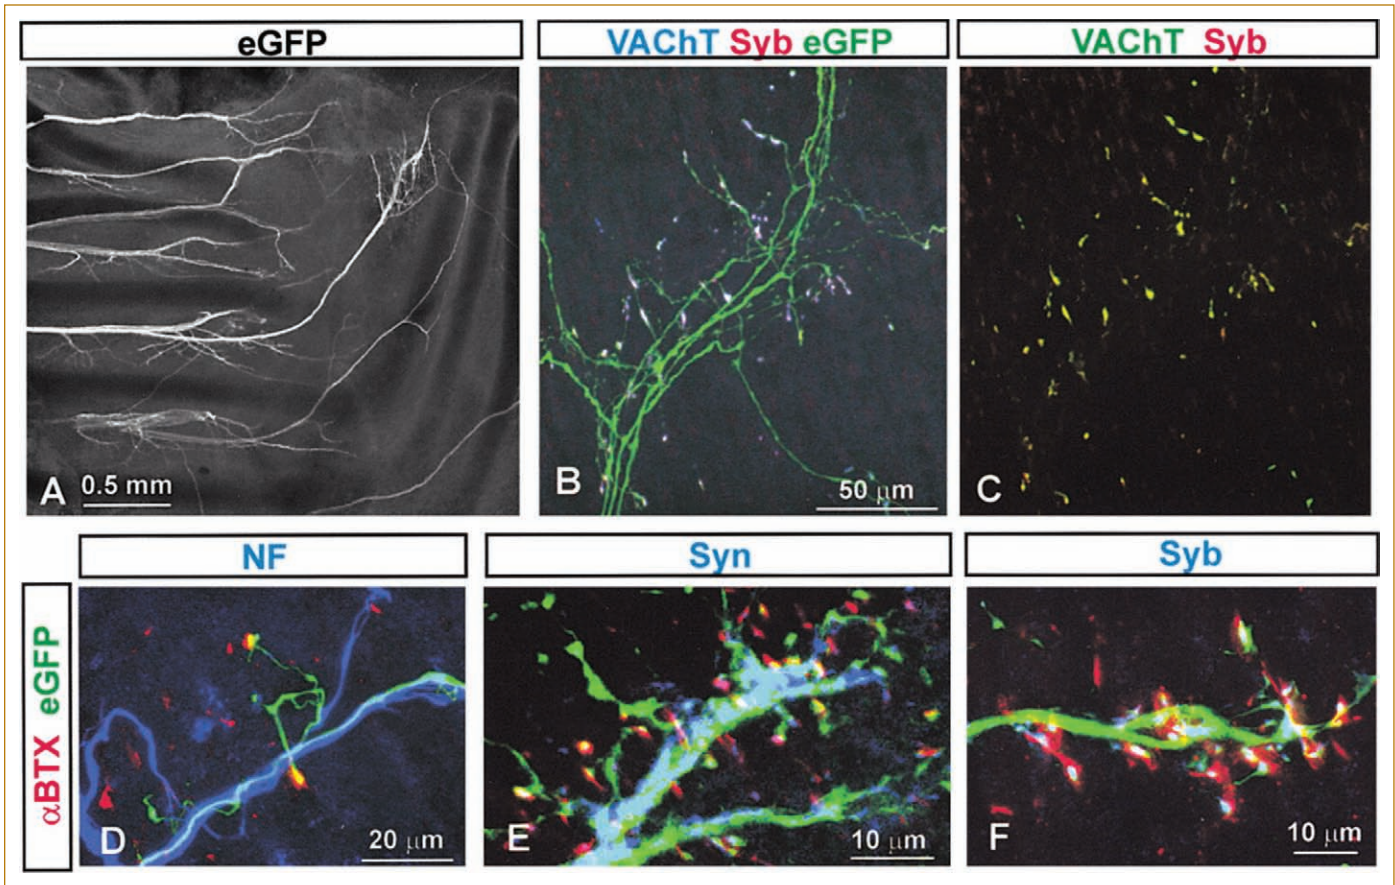

In the same year, John McDonald, David Gottlieb, and Dennis Choi demonstrated for the first time that ES cells that had been induced to become neural cell precursors could be successfully transplanted into the injured spinal cord (McDonald *et al.*, 1999). Examination of the spinal cord nine days after 1 million precursor cells were transplanted

into a cyst caused by contusion injury showed that the cells had survived, grafted, migrated long distances, and differentiated into the three principle neural cell types: neurons, astrocytes, and oligodendrocytes (Figs. 65.9 and 65.10). This group also demonstrated that transplantation was associated with a significant and sizable improvement in function. Their study was the first demonstration that transplanted embryonic precursors can successfully repair the damaged adult nervous system, an important finding, given that conditions in the damaged adult nervous system are much less favorable for regeneration than those in the neonatal spinal cord. Subsequently, Liu and colleagues (2000) demonstrated that precursors derived from ES cells and transplanted into the injured adult nervous system can remyelinate neurons in an anatomically appropriate manner (Fig. 65.11). Furthermore, they showed that oligodendrocytes derived from ES cells functioned normally, myelinating multiple axons in culture, just as they do in the normal nervous system (Fig. 65.12). Using patch clamp analysis, Jim Huettner and John McDonald later demonstrated that the physiologic characteristics of such oligodendrocytes are similar to those of oligodendrocytes taken from the adult spinal cord (Fig. 65.12C and Fig. 65.13). Oligodendrocytes derived from ES cells represent the entire oligodendrocyte lineage, from

**FIG. 65.7.** Embryonic transplantation of motor neurons derived from mouse ES cells. Integration of transplanted ES cell-derived motor neurons into the spinal cord *in vivo*. **(A)** Implantation of HBG3 ES cell-derived motor neuron-enriched embryoid bodies into stage 15–17 chick spinal cord. **(B)** Bright-field/fluorescence image showing eGFP<sup>+</sup> motor neurons in thoracic and lumbar spinal cord, assayed at stage 27 (ventral view). **(C, D)** Location of FACS-sorted ES cell-derived eGFP<sup>+</sup> motor neurons in thoracic spinal cord, assayed at stage 27. eGFP<sup>+</sup> motor neurons are clustered in the ventral spinal cord (D). **(E–J)** Transverse sections through stage 27 chick spinal cord at rostral cervical levels after transplantation of motor neuron-enriched embryoid bodies. Motor neurons are concentrated in the ventral spinal cord and are segregated from transplanted interneurons, labeled by a mouse-specific Lim2 antibody (E). Many ES cell-derived motor neurons coexpress eGFP and Lhx3 (F). ES cell-derived motor neurons (G) and axons (arrow, H) are labeled by rodent-specific anti-NCAM antibody but do not express the chick motor neuron marker protein SC1 (I, J). eGFP<sup>+</sup>, NCAM<sup>+</sup> axons cross the floor plate but do not project out of the spinal cord (arrows, G, H). **(K–N)** Transverse sections of thoracic spinal cord at stage 27, after grafting of embryoid bodies grown with RA (2  $\mu$ M) and anti-Hh antibody (5E1, 30  $\mu$ g/mL). No mouse-derived motor neurons were detected by either eGFP (K) or a mouse-specific anti-HB9 antibody (L). In contrast, many mouse-derived NCAM<sup>+</sup> (M) and Lim2<sup>+</sup> (N) interneurons are present. **(O–Q)** Transverse sections through stage 27 spinal cord at thoracic (O, P) and lumbar (Q) levels after grafting embryoid bodies enriched with motor neurons. eGFP<sup>+</sup> motor neurons are concentrated in the ventral spinal cord. Ectopic eGFP<sup>+</sup> motor neurons are located within the lumen of the spinal cord. eGFP<sup>+</sup> axons exit the spinal cord, primarily via the ventral root, and project along nerve branches that supply axial (O–Q), body wall (O, P), and dorsal and ventral limb (Q) muscles. The pathway of axons is detected by neurofilament (NF) expression. eGFP<sup>+</sup> axons are not detected in motor nerves that project to sympathetic neuronal targets. From Wichterle *et al.* (2002). Reproduced with permission.

**FIG. 65.8.** Anatomic integration of motor neurons derived from transplanted mouse ES cells. Synaptic differentiation of ES cell-derived motor neurons *in vivo*. (A) Whole-mount preparation of stage-35 chick embryonic rib cage. ES cell-derived eGFP<sup>+</sup> motor axons contact intercostal muscles. (B, C) Coexpression of synaptobrevin (Syb) and vesicular acetylcholine transporter (VACHT) in the terminals of eGFP<sup>+</sup> motor axons at sites of nerve contact with muscle. The anti-Syb and -VACHT antibodies recognize mouse but not chick proteins. (D) Neurofilament (NF) and eGFP expression in motor axons that supply intercostal muscles. eGFP<sup>+</sup> axons lack NF expression. The terminals of eGFP<sup>+</sup> axons coincide with clusters of acetylcholine receptors, defined by  $\alpha$ -bungarotoxin ( $\alpha$ BTX) labeling. (E) Coincidence of synaptotagmin (Syn) expression in eGFP<sup>+</sup> motor axon terminals and  $\alpha$ BTX labeling. (F) Coincidence of synaptobrevin (Syb) expression in eGFP<sup>+</sup> motor axon terminals and  $\alpha$ BTX labeling. From Wichterle *et al.* (2002). Reproduced with permission.

early oligodendrocyte precursors to mature, myelinating oligodendrocytes.

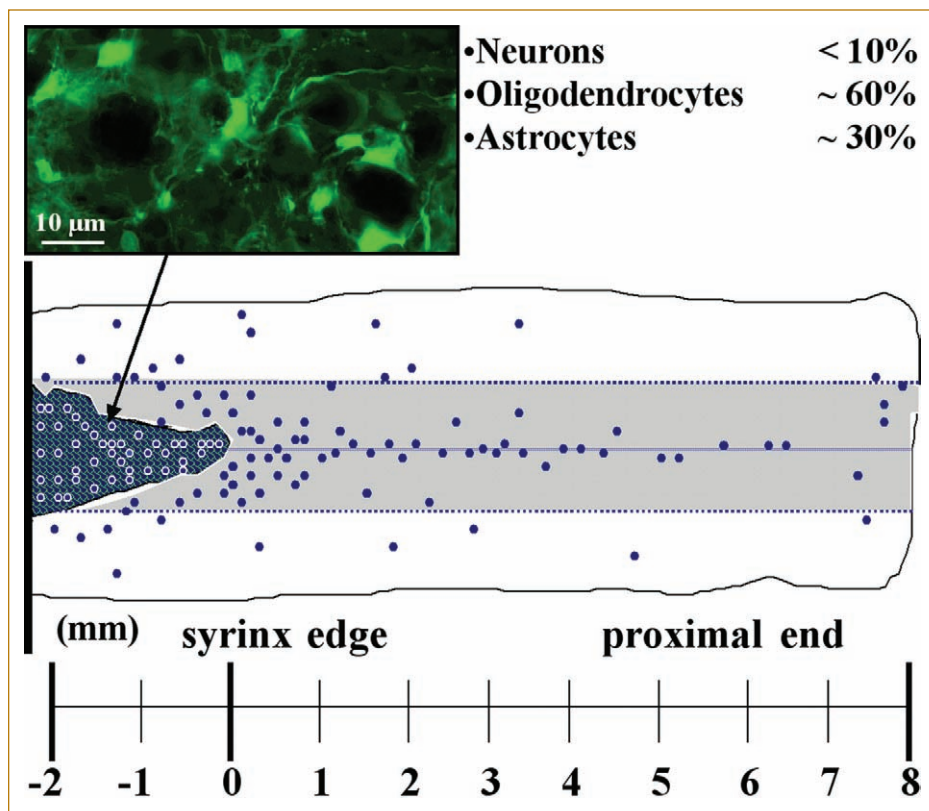

In culture, neurons derived from ES cells differentiate rapidly and spontaneously create neural circuits with anatomical (Fig. 65.14) and physiological evidence of excitatory and inhibitory synapses (Strubing *et al.*, 1995; Finley *et al.*, 1996; Okabe *et al.*, 1996). Substantial neural differentiation is also evident *in vivo* in the model of contusion injury (McDonald *et al.*, 1999), where neurons show extensive axonal outgrowth with presumptive morphological evidence of synapse formation. Moreover, immunological evidence of cholinergic, serotonergic, GABAergic, glycinergic, and glutamatergic neurons has been obtained *in vitro* and *in vivo* (data not shown).

Implantation, survival, and migration of transplanted ES cell-derived precursors in the damaged spinal cord have been verified with real-time polymerase chain reaction (PCR)

and also by using magnetic resonance imaging (MRI) to track oligodendrocytes prelabeled with paramagnetic agents. In both cases, migration up to 1 cm from the transplantation site was evident (Bulte *et al.*, 2001; Lu *et al.*, 2003).

After other groups demonstrated that multiple rounds of transplantation can deliver different types of stem cells to the CNS, our group systematically evaluated intravenous, intraventricular, intrathecal, and interparaneural transplantation of embryo bodies derived from ES cells using our 4-/4+ protocol (four days in culture without retinoic acid followed by four days with retinoic acid). Although some of the cells that were transplanted intravenously entered the CNS, they remained in blood vessels and showed only limited neural differentiation. Intracerebral ventricular administration enabled some transplanted ES cells to be incorporated into the CNS, but this approach had to be discontinued because the cells obstructed the third and

**FIG. 65.9.** In the contusion-injured spinal cord of the rat, ES cell-derived neural precursors survive, migrate, and differentiate following transplantation. The schematic demonstrates the relative distribution of ES-derived cells two weeks after transplantation into the central cavity nine days after spinal contusion injury. The cavity is partially filled, and cells have migrated long distances. Most of the distant cells are identified as oligodendrocytes, while astrocytes and neurons remain restricted to the transplantation site. Left top inset shows gfp-expressing ES cell-derived neural cells.

fourth ventricles, causing hydrocephalus. However, we made a remarkable observation when we transplanted a large number of ES cell-derived neural precursors intrathecally into the lumbar spine (Ao and McDonald, 2002). Three to four months later, ES cells were observed in well-formed tissues surrounding the lumbar sacral nerve roots and extending down the sacral canal. Further evaluation clearly showed that the cells had differentiated into tissue that bore a remarkable resemblance to some components of the normal spinal cord. For example, extensive myelination and cells resembling cholinergic motor neurons were observed. Zones of the peripheral nervous system were also clearly demarcated from the CNS. These results were quite surprising because intraparenchymal transplantation into the spinal cord characteristically produces abnormal macroorganization of cells. Thus, this was the first demonstration that transplanted ES cells can organize themselves into CNS-like tissues. It will now be important to understand the constraints required to produce this degree of self-organization.

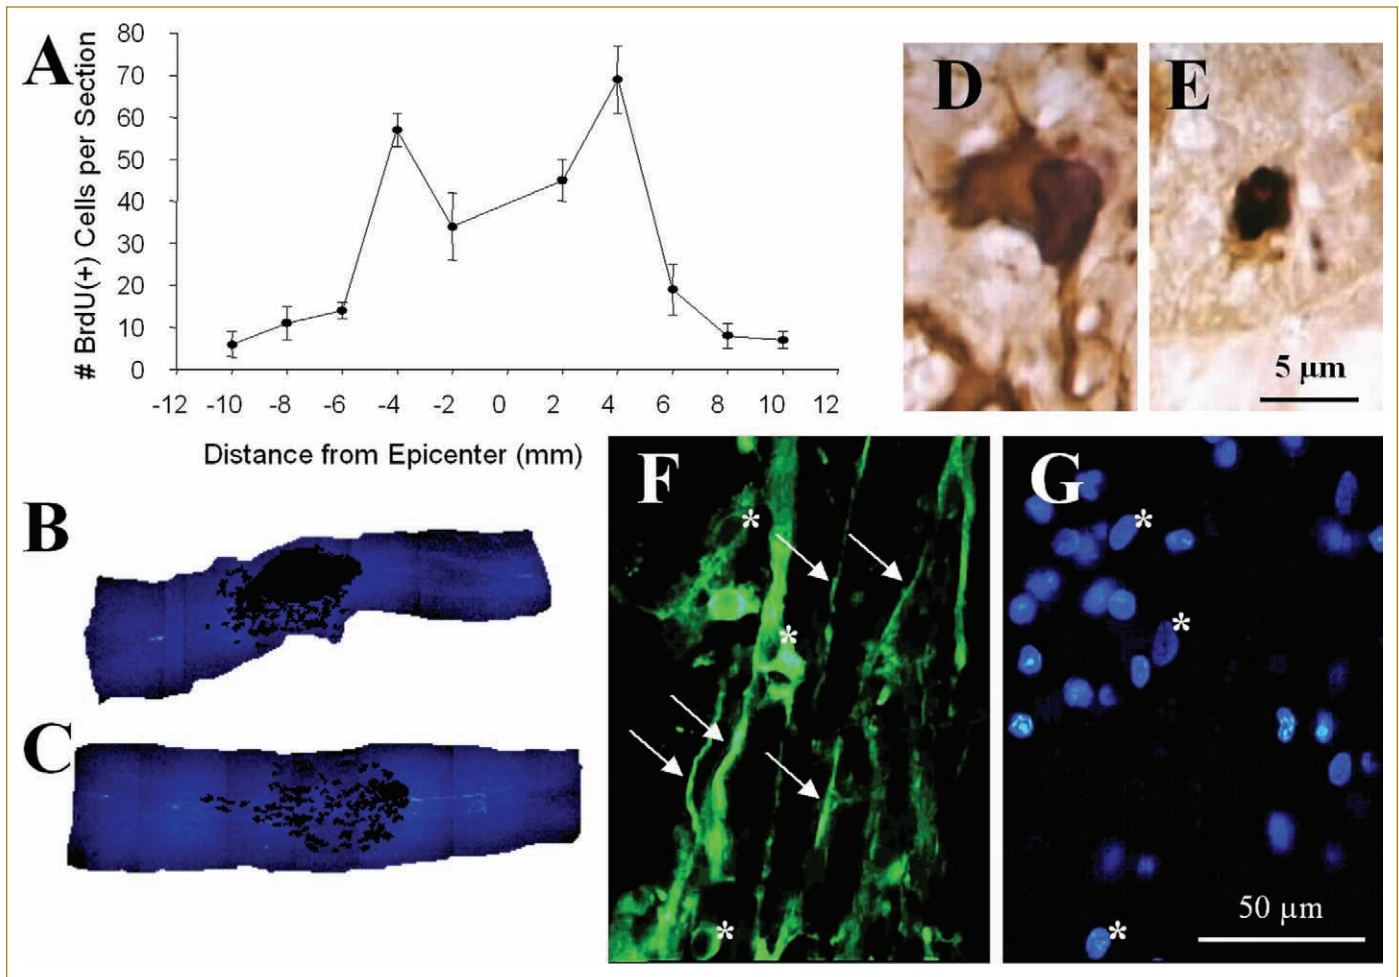

## IX. NOVEL APPROACHES TO CNS REPAIR (Fig. 65.15)

Most neural transplantation studies, including those using ES cell-derived neural progenitors, have used cells to replace cells lost after injury. Given that we do not know

which types of differentiated cells are required for repair, neural precursors may be ideal for this purpose because environmental clues can decide their developmental fate (Liu *et al.*, 2000; Cao *et al.*, 2002; Murray and Fisher, 2001). Moreover, such precursors can serve as bridges to support axonal regrowth (Bunge, 2002).

To try to overcome the physical and chemical constraints imposed by the injured nervous system, ES cells are often genetically altered so they will deliver growth molecules, such as neurotrophin-3, after transplantation (Novikova *et al.*, 2002; Murray and Fisher, 2001; Tuszynski *et al.*, 2002), and they are particularly well suited to this task. McDonald and Silver recently adopted a novel approach to overcoming restraints by showing that early progenitors of ES cells can phagocytize key inhibitory molecules in glial scar tissue (Vadivelu *et al.*, 2003). These cells therefore created an inhibitor-free bridge over which axons rapidly sprouted from the transplant into normal cord. By nine days after transplantation, axons from the graft had grown up to 1 cm — a rate of more than 1 mm per day! This rate is similar to that seen in the normal embryo (Mouvetroux *et al.*, 2000).

Another novel approach is to use stem cell transplantation to limit the secondary injury that occurs after nervous system injury (Teng *et al.*, 2002). For example, we recently demonstrated that transplanting ES cells can limit the delayed death of neurons and oligodendrocytes. Since most

**FIG. 65.10.** BrdU-labeled ES cell-derived cells two weeks after transplantation. Mean  $\pm$  SEM BrdU-labeled nuclei per 1-mm segment in longitudinal sections. **(A)** Hoechst 33342-labeled sections 42 days after injury, transplanted with vehicle **(B)** or ES cells **(C)** nine days after injury. Corresponding nuclei are marked by asterisks **(G)**. Modified from McDonald *et al.* (1999) with permission.

transplantations are performed at the time of injury, it is possible that many of their results may be attributable to this neuroprotective role. It seems clear that even genetically unmodified ES cells release large quantities of growth factors.

Although replacing lost neurons is difficult, it might be possible to use neuronal replacements to create bridging circuits across the injury site. Descending axons could synapse onto ES cell-derived neurons that subsequently synapsed onto key pattern generators in the lower spinal cord. More global delivery of neurotransmitters via synaptic or nonsynaptic mechanisms might enhance functions such as locomotion. Previous work by others has demonstrated that release of noradrenergic and serotonergic neurotransmitters can stimulate and enhance the central pattern generator for locomotion (Rossignol *et al.*, 1998). More recent work indicates that release of brain-derived neurotrophic

factor and neurotrophin-3 can perform this function (Ankeny *et al.*, 2001).

Because ES cells are embryonic in nature, neural progenitors derived from them may be able to reprogram the adult CNS so that damage can be repaired (Tada *et al.*, 2001). ES cells are also unique in that they have the potential to replace cells derived from multiple embryonic germ layers. In the CNS, it will be important to replace lost nonneural cells as well as neural cells to regain normal CNS function, such as neovascularization. Growing recognition of the link between neovascularization and neurogenesis is strengthening this approach. We recently found that ES cells in transplanted 4-/4+ embryoid bodies differentiate into both neural cells and vascular endothelial cells (unpublished observations).

In the embryo, stem cells differentiate into motor neurons and grow toward muscle, where they form neuro-

**FIG. 65.11.** Cells derived from ES oligospheres can migrate and myelinate axons when transplanted into dysmyelinated spinal cords of adult *shiverer* mice, which lack the gene for myelin basic protein (MBP). Transplanted cells were identified by cell tracker orange (CTO) epifluorescence (red) or immunoreactivity for MBP (green). Hoechst 33342 (blue). CTO-labeled cells aligned with native intrafascicular oligodendrocytes in white matter (**A**, **B**). An ES cell-derived (MBP<sup>+</sup>) oligodendrocyte (asterisk) with longitudinally oriented processes (white arrows) is shown in panels **C** and **D**. Red arrows mark probable myelination around an adjacent axon (**C**). Little MBP immunoreactivity is seen in white matter in a longitudinal section of spinal cord from a mouse that received a sham transplantation (**E**). A gradient of MBP immunoreactivity centers on the site of ES cell transplantation (**F**). Panel **G** (high magnification) shows intrafascicular oligodendrocyte nuclei (blue) and MBP immunoreactivity (green), two indications of axonal myelination (white arrows), in white matter from a mouse transplanted with ES cells. The spatial distribution of MBP immunoreactivity one month after ES cell transplantation is shown at low magnification (**H**), with corresponding Hoechst 33342 counterstaining (**I**). White arrows indicate the center of the transplanted site. Transmission EM shows four loose wraps of myelin, the maximal number of layers typically seen around axons in control animals (red arrow, **J**), and nine or more compact wraps around axons from the transplanted area (red arrow, **K**). Shiverer-mutant mice lack a functional MBP gene that is required to form mature compact myelin; therefore, the presence of mature compact myelin is a standard for transplant oligodendrocyte-associated myelin. Scale bars: A–I = 10 μm; J, K = 0.3 μm. Reproduced with permission from Liu *et al.* (2000).

**FIG. 65.12.** ES cells produced mature oligodendrocytes with normal anatomical features of myelination and physiological response to neurotransmitters. Reproduced in adapted form with permission from Liu *et al.* (2000).

**FIG. 65.13.** Excitatory (*top*) and inhibitory (*bottom*) synaptic transmission between neurons derived *in vitro* from mouse ES cells. Action potentials were evoked in the presynaptic neuron by current injection. Excitatory postsynaptic currents, blocked by superfusion with the selective glutamate receptor antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX; 10 micromolar), were recorded under voltage clamp. Arrows point to an autaptic excitatory synaptic potential that is also blocked by CNQX. Inhibitory synaptic currents were evoked in a different ES cell pair and tested sequentially with the antagonists bicuculline and strychnine, which are selective for gamma-aminobutyric acid (GABA) and glycine receptors, respectively. For this cell pair, only the postsynaptic currents are shown. Transmission was blocked by strychnine, indicating that glycine was the transmitter. Other presynaptic cells evoked bicuculline-sensitive synaptic currents, indicating that GABA mediated transmission (not shown).

muscular junctions. Using ES-derived motor neurons to replace lost motor neurons at injured segments will not enhance function because chronically denervated muscle is unable to reassemble functional neuromuscular junctions. However, transplantation might avoid the long-term muscle wasting that results from denervation. To maintain denervated muscle, for example, it might be possible to transplant ES cells into the distal nerve stump or directly into the muscle. Once in place, the transplanted cells could differentiate into motor neurons. If they were genetically altered, the motor neurons could be selectively removed once the repair was properly achieved.

More recent studies are beginning to combine stem cells, including ES cells, with biomaterials. The advent of nanotechnology should further enhance this approach (Lockman *et al.*, 2002).

Finally, remyelination is one of the most pragmatic approaches to restoring function to the damaged spinal cord. Because many potentially functional connections remain in the outer donut of surviving tissue, appropriate remyelination could substantially improve function. One must consider, however, that dysmyelination rather than demyelination is the biggest problem in the damaged nervous system. Often, inappropriate myelination is more harmful than no myelination at all.

## X. TOWARD HUMAN TRIALS

Some of the animal studies described previously have prompted early human safety trials of ES cell transplantation. Most have focused on Parkinson's disease, where unforeseen exaggeration of dystonia has limited advances

**FIG. 65.14.** ES cells differentiate into neurons that spontaneously create neural circuits. Presumptive presynaptic sites (red) oppose dendrites (green) in (A) and (B). (C) and (D) demonstrate ultrastructural characteristics of synaptic profiles *in vitro*.

**FIG. 65.15.** Novel approaches to spinal cord repair using ES cells. Remyelination is one of the most pragmatic approaches to restoring function to the damaged spinal cord. ES cell-derived precursors can serve as bridges to support axonal regrowth. They can phagocytize key inhibitory molecules in glial scar tissue. These cells therefore created an inhibitor-free bridge over which axons sprouted rapidly from the transplant into normal cord. Newly generated neurons can be used to create bridging circuits across the injury site. ES cell transplantation can limit the secondary injury. To try to overcome the constraints of the injured nervous system, ES cells are often genetically altered so that they will deliver growth molecules, such as NT3, after transplantation. Because ES cells are embryonic in nature, their progenitors may also be able to reprogram the adult CNS to optimize spontaneous host regeneration. Replacement of nonneural cells as well as neural cells will be important for regaining normal CNS function, such as neovascularization. ES cells can have similar applications in the peripheral nervous system.

in transplantation therapy (Ma *et al.*, 2002). Phase I human trials for repairing the spinal cord are also under way. They include transplantation of porcine-derived stem cells for the purpose of remyelination (Diacrin; <http://www.diacrin.com>) as well as allogeneic transplantation of olfactory ensheathing glia (Carlos Lima; Lisbon, Portugal). Although safety data are not yet available, it is important to note that such trials are paving the way for further uses of ES cells. With the recent advent of human ES cells, human transplantation appears more feasible, though somatic transplantation will be required to ensure a genetic match. Such manipulation of cells raises many regulatory concerns that must be addressed before clinical trials can move forward. The recent demonstration of *in vitro* oocyte generation from mouse ES cells raises the possibility that ethically acceptable procedures for human nuclear transfer may soon be available (Hubner *et al.*, 2003).

## XI. CONCLUSIONS

Studies of neurotransplantation for repairing the damaged nervous system are making good progress. Early animal studies showed that mouse ES cells can replace neurons, astrocytes, and oligodendrocytes, instigate appropriate remyelination, and even improve locomotion. As is the case for all transplantation studies, however, the mechanisms underlying functional improvement remain unclear. Nevertheless, ES cells offer a novel approach to deciphering these mechanisms. For the first time, ES cell genetics is allowing investigators to track transplanted cells that have been engineered to express green fluorescent protein. This and other types of genetic modification permit one to track

the integration and differentiation of ES cells, assess behavioral recovery, selectively remove the cells to see whether recovery wanes, and insert more cells to see if functional recovery occurs anew. This proof of principle will be required to identify mechanisms in neural repair.

Although it is impossible to predict the future of the field, it is clear that murine and human ES cells are tools that will revolutionize neurobiology and neural transplantation

by providing the unprecedented ability to selectively deliver key growth and regulatory factors. Also, ES cell transplantation promises to be one of the greatest potential therapies for chronic nervous system disorders. Only the future will reveal its full potential for treating human disease and disability, but it is possible to say with confidence that ES cells will have a major impact on repairing the human CNS within our lifetimes.

## XII. ACKNOWLEDGMENTS

We would like to thank the people in our laboratory who have contributed to this work over the years and also our collaborators: Jeff Bulte at NIH; Dennis W. Choi, David I. Gottlieb, David Gutmann, Chung Hsu, Mark F. Jacquin, Gene Johnson, and Carl Laurysen at Washington University in St. Louis. This team obtained a program project grant from the National Institutes of Health (NIH; NS39577) to evaluate the potential of embryonic stem cells to repair

spinal cord injury. We would also like to thank our animal technicians, who express rodent bladders three times daily, seven days a week, including holidays (Joan Bonnot, Joseph Galvez, Brandy Jones, Amy Hansen) and our TC staff, who passage ES cells every other day, endlessly (Ashley Johnson, Laura Luecking, Becky Purcell). This work was supported by NINDS and NIDCR grants NS39577, NS40520, NS45023, and DE07734.

### I. INTRODUCTION

Deafness is this country's number-one disability, with hearing loss affecting more than 35 million individuals. There is an increasing ability to use tissue engineering to prevent acquired deafness and to restore hearing following deafness. Hearing loss and cochlear damage from noise, ototoxic drugs, trauma, disease, and perhaps even aging can be reduced by relieving oxidative stress to the cochlea and enhancing endogenous protective systems with agents such as neurotrophic factors, heat shock proteins, and antioxidants. Genetic modification to induce regeneration of hair cells following their loss has now been shown in animal models and may soon become clinically feasible. Stem cells are also being developed as a mechanism to replace lost hair cells or auditory nerve. Survival factors can be applied to the cochlea to improve auditory nerve survival following deafness and to induce regeneration of its peripheral processes. Major advances have also been made in region-specific delivery of therapeutics to the cochlea to allow these interventions, including gene transfer and microcannulation. Auditory prostheses also provide for return of hearing following deafness, with significant improvements occurring in cochlear prostheses as well as in development of central auditory prostheses. Prostheses can also provide a mechanism

for application of therapeutics through microchannels. Biopolymers on and associated with prostheses not only can improve their function and histocompatibility but also can provide for other mechanisms of therapeutics.

Hearing loss affects individuals in all age groups. It increases with age, affecting one in three over the age of 65 and 50% of individuals over the age of 75. With the increased longevity of our population, this disability is also increasing. Approximately one-half of all hearing losses are thought to be of genetic etiology. Acquired deafness affects one in four to five individuals and can occur from a variety of causes, including noise, drugs, trauma, disease, and aging. It is obviously important to develop interventions to help to prevent hearing loss and treatment to restore hearing after deafness. In the latter case, major progress has been made in inducing regeneration of the sensory hair cells, whose loss results in profound deafness. In addition, recent advances in our understanding of molecular mechanisms as well as new developments in cochlear prostheses also provide promise for new and effective treatments for protection from acquired and genetic deafness and better restoration of hearing. This chapter discusses the basis and methods for achieving such interventions.

## II. INTERVENTIONS TO PREVENT HEARING LOSS/COCHLEAR DAMAGE

### Oxidative Stress

Oxidative stress, the overproduction of reactive oxygen species (ROS; free radicals) in the cell, now appears to be recognized as a common mechanism by which many traumatic insults, including noise, ototoxic drugs, and possibly aging, cause damage to the inner ear. The formation of ROS, such as superoxide, hydroxyl radical, and nitric oxide, may occur by different mechanisms for each stress, but in each it appears to occur early and throughout the traumatizing events. Normally contained within a physiological range by endogenous antioxidant systems, ROS in excess can cause cellular damage, and the resulting redox imbalance will trigger cell death pathways of apoptosis and necrosis.

### Prevention of Aminoglycoside-Induced Hearing Loss

Aminoglycoside antibiotics, a class of drugs that includes neomycin, kanamycin, tobramycin, amikacin, and gentamicin, can exert a plethora of effects on afflicted tissues, such as the block of calcium channels and interference with enzymatic mechanisms (Forge and Schacht, 2000). ROS formation has been causally linked to the adverse effects on the inner ear, both through studies of the mechanism of these drugs *in vitro* and *in vivo* and perhaps most compellingly through studies of protection from these adverse effects by means of antioxidants.

ROS can be formed by the ability of aminoglycosides to chelate iron and abstract electrons from donors such as polyunsaturated fatty acids (Priuska and Schacht, 1995; Lesniak *et al.*, 2005). The propensity to accelerate ROS formation is shared by all aminoglycoside antibiotics (Sha and Schacht, 1999a) and is also evident in organ culture of inner ear tissues and the cochlea *in vivo* (Clerici *et al.*, 1996; Hirose *et al.*, 1997; Jiang *et al.*, 2006a). In addition, aminoglycosides can activate redox-dependent molecular signaling pathways linked to Rho-GTPases, which can, in turn, activate NADPH oxidase, an enzyme responsible for the formation of superoxide radicals (Jiang *et al.*, 2006b).

On oxidative insult, complex signaling pathways of cell death and survival are initiated, a network of interfacing signaling systems involving a variety of transcription factors and proteases and intracellular organelles such as mitochondria and lysosomes. Indicative of this complexity, cell death by aminoglycosides includes both apoptosis and necrosis of hair cells in cochlear and vestibular organs (Nakagawa *et al.*, 1998; Ylikoski *et al.*, 2002; see also Forge and Schacht, 2000), and both caspase-dependent and caspase-independent pathways appear to contribute to hair cell pathology. Studies implicating caspase-3 in hair cell death have been performed, primarily *in vitro* with explant cultures and isolated cells or in the vestibular system (e.g.,

Matsui *et al.*, 2004). The JNK apoptotic pathway is also often implicated, since pharmacological inhibitors (e.g., CEP-1347) can offer some protection *in vitro* from aminoglycosides (Pirvola *et al.*, 2000; Bodmer *et al.*, 2002). Like the caspase pathway, involvement of the JNK pathway is reported mostly in cultured explants but may contribute to the overall pattern of cell death *in vivo*. A dominance of caspase-independent cell death emerges in a chronic drug treatment model, where the onset of cochlear deficit is delayed and continues to develop after the cessation of treatment, akin to the clinical situation. In this model, activated calpain and cathepsins are the major mediators of cell death (Jiang *et al.*, 2006a).

The establishment of oxidant stress as the mechanism underlying both apoptotic and necrotic cell death in ototoxicity provides a basis for a rational approach to prevention. For example, small synthetic molecules designed to inhibit one of the many steps in the apoptotic cascade are a potential approach to stave off cell death. For a clinical application, however, a systemic application of such powerful signaling molecules may have far-ranging physiological consequences, particularly when applied to drug treatment, which may last for weeks. Local gene therapy, the process of virally introducing a gene into a tissue, may be more suitable in such a situation (Kawamoto *et al.*, 2004). However, given the complexity of cell death mechanisms, targeting a single pathway may not be sufficient.

A potentially more feasible method of prevention would be antioxidant therapy, which has become a successful clinical approach to many pathologies that involve free radicals. This type of intervention would also act directly on the ROS upstream of the ensuing cell death pathways and therefore suppress toxic mechanisms at the very onset. A wide variety of antioxidant molecules can indeed attenuate hearing loss and cell death *in vivo* while suppressing free radical formation (Song and Schacht, 1996; Song *et al.*, 1997, 1998; Conlon and Smith, 1998; Conlon *et al.*, 1999; Sha and Schacht, 2000). The attenuation achieved in animal models was quite dramatic. For example, a gentamicin-induced hearing loss of 60–80 dB could be reduced to a negligible loss of 10 dB or less (Song *et al.*, 1997). Since neither the serum levels of the drugs nor their antibacterial efficacy were compromised, antioxidant therapy appeared promising for a clinical application.

A clinically feasible prophylactic therapy requires drugs that by themselves are nontoxic and easily administered to the patients. Among the drugs surveyed in animal experimentation, compounds such as lipoic acid or D-methionine appear useful because they are available for clinical application in other contexts (for a summary of therapeutic opportunities, see Rybak and Whitworth, 2005). However, a particularly promising compound was salicylate (Sha and Schacht, 1999b). Aspirin (acetyl salicylate) is hydrolyzed, within minutes after ingestion, to salicylate and might therefore serve as a protective medication.

The efficacy of aspirin was recently tested in a randomized double-blind and placebo-controlled study in patients receiving gentamicin for acute infections (Sha *et al.*, 2006). Fourteen of 106 patients (13%) met the criteria of hearing loss in the placebo group, while only 3 out of 89 (3%) sustained a hearing loss in the aspirin group. Aspirin did not influence gentamicin serum levels or the course of therapy. These results indicate that therapeutic protection from aminoglycoside ototoxicity may be extrapolated from animal models to the clinic. Furthermore, simple antioxidants and even medications as common as aspirin may hold significant promise to attenuate the risk of aminoglycoside-induced hearing loss.

### Prevention of Noise-Induced Hearing Loss

The mechanisms of noise-induced pathology are potentially more complex than those for drug-induced ototoxicity, including not only the formation of reactive oxygen species but also vasoconstriction and direct mechanical damage. In addition, the sources of noise trauma can be highly variable, ranging from a single high-energy impact, such as an explosion, to impulse noise, to chronic noise exposure at various levels of intensity. Each of these conditions may induce variations in the mechanism of ROS formation or variations on cell death and survival pathways. Furthermore, while a protective therapy can be timed with drug administration, patients may report noise-induced hearing loss days, months, or years into the trauma. To what extent a delayed intervention may be successful is yet another question that remains to be resolved.

As with aminoglycosides, there is good evidence that ROS are formed in the inner ear following intense sounds (Ohlemiller *et al.*, 1999), specifically in the stria vascularis (Yamane *et al.*, 1995) and the organ of Corti (Ohinata *et al.*, 2000a). Indicators of ROS formation can be detected at the onset of the noise exposure (Ohinata *et al.*, 2000a) and may persist for hours (Yamane *et al.*, 1995) or even days (Yamashita *et al.*, 2004). Attesting to the importance of endogenous antioxidants, decreased glutathione in the inner ear enhances noise trauma, while dietary supplementation with glutathione attenuates these effects (Yamasoba *et al.*, 1998; Ohinata *et al.*, 2000b; Henderson *et al.*, 2006).

While the precise origin of ROS in the cochlea following noise exposure remains somewhat speculative, there are several sources most likely to contribute. A surge of superoxide radicals followed by chain reaction formation of other free radicals (via Fenton-type reactions) may be due to increased mitochondrial activity, a prolonged tissue hypoxia due to vasoconstriction (Brown *et al.*, 2003), and a rebound hyperfusion (Thorne *et al.*, 1987). Reactive nitrogen species may arise from the activation or induction of the enzyme nitric oxide synthase. The different isoforms of this enzyme serve a variety of physiological processes in normal tissue physiology, and the product of the enzymatic reaction, nitric oxide, is an important second messenger molecule. When

produced in excess, not only is nitric oxide potentially damaging as a free radical, but it can also combine with superoxide to produce the highly reactive and destructive peroxynitride. Nitric oxide levels can rise after noise exposure (Shi *et al.*, 2002; Yamashita *et al.*, 2004a), perhaps as a consequence of an enhanced release of excitatory amino acids (Puel *et al.*, 1994, 1996), and may contribute to the overall pathophysiology of noise-induced hair cell loss.

Multiple cell death pathways — partly independent and partly overlapping — may be triggered by the spectrum of radicals generated in response to noise. The fact that both necrosis and apoptosis are observed in noise trauma attests to the existence of multiple cell death pathways (Henderson *et al.*, 2006). This notion is also supported by the emergence of caspase-dependent and caspase-independent cell death pathways and the involvement of transcription factors that code for different signaling cascades, such as AP-1, endonuclease G, and the calcineurin-related activation of BCL-2 family proteins (Hu *et al.*, 2002; Yamashita *et al.*, 2004b; Matsunobu *et al.*, 2004; Vicente-Torres and Schacht, 2006).

Restoring redox balance is therefore also one of the potential means of intervention in noise-induced hearing loss, the other being a manipulation and interference with cell death pathways. The latter has been done successfully in animal experimentations *in vivo* (Pirvola *et al.*, 2000; J. Wang *et al.*, 2003), but similar concerns may arise here as in the prevention of drug-induced hearing loss, in that such systemic intervention in important physiological processes may have unwanted consequences. Other approaches successful in animals may also be impractical for the clinic. For example, the up-regulation of antioxidant defenses by systemically administered R-phenyl isopropyl adenosine has adverse physiological effects (Hu *et al.*, 1997). A local application may bypass such a problem but is more invasive and affords less control over drug concentrations.

Nevertheless, antioxidant therapy does hold promise as an interventional strategy, with an appropriate choice of drugs (see Lynch and Kil, 2005). Noise-induced hearing loss can be attenuated effectively by scavengers such as superoxide dismutase and allopurinol (Seidman *et al.*, 1993), antioxidants, and iron chelators (Yamasoba *et al.*, 1999) and by antioxidant drugs that may have clinical appeal, such as ebselen (Pourbakht and Yamasoba, 2003) or N-acetylcysteine (Kopke *et al.*, 2000). Multidrug combinations are promising, for example, acetyl-L carnitine with D-methionine or N-acetylcysteine (Kopke *et al.*, 2002, 2005). Alternative strategies aimed at vasodilation and providing adequate blood flow to the cochlea during noise exposure may also indirectly relate to ROS formation. Drugs such as pentoxifylline and sarthran improved blood flow to the cochlea and also reduced the temporary effects of noise exposure (Latoni *et al.*, 1996; Goldwin *et al.*, 1998). Magnesium supplementation likewise maintains cochlear blood flow under noise exposure and reduces the resulting hearing loss (Haupt and Scheibe, 2002).

The translation of these findings from animal models to practical situations in humans has been partially successful in tests on populations exposed to high levels of noise during military exercises and leisure activities. Daily supplementation with magnesium reduced the incidence of permanent threshold shifts in military recruits from 21.5% to 11.2% (Attias *et al.*, 1994) and, likewise, reduced temporary threshold shifts in a group of young volunteers (Attias *et al.*, 2004). In contrast, a group of nightclub visitors taking *N*-acetyl cysteine sustained the same temporary threshold shift as the control group (Kramer *et al.*, 2005, cited in Lynch and Kil, 2005). Ongoing trials on U.S. Army and Navy recruits currently explore the efficacy of *N*-acetyl cysteine and of ebselen (Lynch and Kil, 2005).

While most strategies for interventions rely on applying the protective treatment prior to or concomitant with noise exposure, recent evidence indicates that the formation of free radicals continues for days following noise exposure (Yamashita *et al.*, 2004a) and that, consequently, an antioxidant treatment may still be effective for a short period post-exposure (Yamashita *et al.*, 2005).

### Heat Shock Proteins

Heat shock proteins (HSPs) provide another natural protective mechanism. HSPs can achieve their protective role by influencing the stress-related denaturation of proteins (either reducing the denaturation or enhancing renaturation and regaining the correct tertiary structure), as chaperones or through an influence on cell death cascades. Several families of HSPs (commonly grouped by their molecular weights) include HSP 25/27, HSP 32, and HSP 70/72. Expression of the inducible form of HSP 70 in the cochlea has been shown with heat (Dechesne *et al.*, 1992; Yoshida *et al.*, 1999), transient ischemia (Myers *et al.*, 1992), noise (Lim *et al.*, 1993), and ototoxic drugs (Oh *et al.*, 2000). This expression is generally found in the sensory hair cells and is transient, peaking three to seven hours following the stress. HSP 27 is found constitutively (without the need for induction by stress) and has a more widespread distribution, not only in sensory hair cells, but in supporting cells and the lateral wall tissues (Leonova *et al.*, 2002). Levels increase following stress. HSP 32 has a small constitutive expression and is up-regulated following stress in hair cells and stria vascularis (Fairfield *et al.*, 2004).

A protective role of HSPs in the inner ear is suggested by two types of studies. In one type of study, HSP levels are up-regulated by an initial stress, either low-level noise (Altschuler *et al.*, 1999a) or heat (Yoshida *et al.*, 1999), followed by a noise exposure that would normally cause a significant hearing loss. Either preexposure resulted in a significant (30-dB) reduction in noise-induced hearing loss and hair cell loss. Mikuriya *et al.* (2005) showed reduced hearing loss and less hair cell loss from noise in guinea pigs in which geranylgeranylacetone was used to increase induction of heat shock proteins. A second type of study examines

heat shock factor 1 (HSF1), a major transcription factor for the HSPs, which has been shown to be present in hair cells and stria vascularis in the rodent cochlea (Fairfield *et al.*, 2002). In mice in which HSF1 has been knocked out, there is decreased protection from noise, with increased hearing loss and increased loss of hair cells (Fairfield *et al.*, 2005; Sugahara *et al.*, 2003).

### Neurotrophic Factors

Neurotrophic factors play an important role in the development of the cochlea, in regulating differentiation of sensory and neuronal elements, as well as in the formation of afferent and efferent connections (for reviews, see Fritsch *et al.*, 2003, 2006). Many neurotrophic factors and/or their receptors remain in the mature cochlea, including GDNF, NT3, and BDNF (Ylikoski *et al.*, 1993, 1998; Fritsch *et al.*, 2006; Stöver *et al.*, 2000, 2001), where they play a role in maintenance and protection. Neurotrophic factors can have a protective action through an influence on ROM or intervention in the cascade of events induced by ROM formation to block cell death. Removal of neurotrophic factors leads to an increase in reactive oxygen species, which can induce cell death through the apoptotic pathways discussed previously. While removal of neurotrophic factors is therefore pro-apoptotic, neurotrophic factors themselves can also induce pro-survival pathways and provide protection. Neurotrophic factors may reduce oxidative stress-driven increases in intracellular  $\text{Ca}^{2+}$  (Hegarty *et al.*, 1997; Mattson *et al.*, 1995; Mattson and Furakawa, 1996) through induced expression of calcium-binding proteins (Collazo *et al.*, 1992; Cheng and Mattson, 1994) or antioxidant enzymes (Mattson *et al.*, 1995; Mattson and Furakawa, 1996).

Infusion of neurotrophins into the inner ear fluids prior to stress provides protection from hearing loss (for reviews, see Altschuler *et al.*, 1999a; Kopke *et al.*, 1999; LePrell *et al.*, 2003; Miller *et al.*, 1998; Miller *et al.*, 1999). When levels of glial line-derived neurotrophic factor (GDNF) or neurotrophin 3 (NT3) are increased in the inner ear prior to noise overstimulation or the administration of ototoxic drugs there is significant protection, with decreased hearing loss and hair cell loss (Altschuler *et al.*, 1999b; Keithley *et al.*, 1998; A. M. Miller *et al.*, 1999; Park *et al.*, 1998; Shoji *et al.*, 2000, 2002; Yagi *et al.*, 1999). This protection is less effective if the neurotrophic factors are provided after the stress rather than before, suggesting that they play a greater role in protection than in repair. BDNF and FGF were less effective in preventing hair cell loss (Shoji *et al.*, 2002; Yamasoba *et al.*, 2001).

## III. HAIR CELL REGENERATION

Once hair cells of the mammalian cochlea are lost, they will not regenerate spontaneously. The only possible way to restore hearing via biological means is by replacing the missing hair cells. Such therapy is being developed via several different approaches, including the use of stem cells,

enhancement of cell proliferation, and reactivation of developmental signals that regulate hair cell development. Knowledge of the developmental genes that regulate the proliferation and differentiation of hair cells during development is essential for designing hair cell regeneration strategies. Technological means for manipulating gene expression in the mature ear are also necessary. Progress in these two fields has allowed for important recent breakthroughs in attempts to induce cochlear hair cell regeneration.

One important goal for treating the deaf cochlea is to increase the number of cells and to direct the differentiation of some of the new cells toward hair cell phenotype. The *p27<sup>Kip1</sup>* gene is expressed in nonsensory cells and keeps them quiescent (Lowenheim *et al.*, 1999; P. Chen and Segil, 1999). Mice with deficient expression of the *p27<sup>Kip1</sup>* gene exhibit organ of Corti cells with an excessive number of hair cells. It appears that in the absence of cell-cycle arrest, cells continue to proliferate after they normally would have stopped had *p27<sup>Kip1</sup>* been active. Interestingly, mice with this induced mutation have a severe hearing loss, despite the large number of hair cells (P. Chen and Segil, 1999; Kanzaki *et al.*, 2006). Nevertheless, the ability to use genetic manipulation for inducing growth of new hair cells is a considerable breakthrough that can lead to feasible clinical applications with further refining and advancing of the technology. Inhibition of the cell cycle can also be removed by blocking expression of other genes, including *Ink4d* and *Rb1* (P. Chen *et al.*, 2003; Sage *et al.*, 2005), leading to extranumerary hair cells in the tissue. The genetic manipulations that are common in the mouse model cannot be done in humans, for both technical and ethical reasons. However, further development of the technology for gene transfer and manipulation in the somatic cells of a target tissue may help advance this approach for clinically relevant hair cell regeneration therapy.

Hair cells and supporting cells develop from common progenitor cells (Fekete and Wu, 2002). Their phenotype is determined by a set of genes expressed in a sequence and influencing neighboring cells in a cross-interactive way. Some of the genes that signal for the differentiation of hair cells have been identified (Fekete and Wu, 2002; Barald and Kelley, 2004; Woods *et al.*, 2004; Zine, 2003; Bermingham *et al.*, 1999; Bryant *et al.*, 2002). Knowledge of these genes helped in the design of a strategy for inducing hair cell regeneration based on forced expression of the hair cell developmental genes in nonsensory cells that remain in the mature deaf cochlea. Thus, the goal of this genetic manipulation is to induce a phenotypic conversion in supporting cells and to turn them into hair cells. Birds and other non-mammalian vertebrates can regenerate hair cells spontaneously (Ryals and Rubel, 1988; Corwin and Cotanche, 1988) using a mechanism of transdifferentiation, with or without a proliferative state (Raphael, 1992; Stone and Cotanche, 1994; Adler and Raphael, 1996; Roberson *et al.*, 1996).

To induce expression of developmental genes in the supporting cells of the deaf organ of Corti, genes were delivered via adenovirus vectors that were inoculated into the scala media (Ishimoto *et al.*, 2002). *Atoh1* is a gene encoding a transcription factor that is necessary and sufficient for hair cell differentiation in the developing epithelial ridge (Woods *et al.*, 2004; Bermingham *et al.*, 1999; Zine *et al.*, 2001; Doetzlhofer *et al.*, 2004). Overexpression of *Atoh1* (or its homolog) resulted in the appearance of cells that had the surface morphology of hair cells in the auditory epithelium (Kawamoto *et al.*, 2003; Izumikawa *et al.*, 2005). These cells were presumed to be new hair cells and were found in the organ of Corti proper as well as in an ectopic location adjacent to the organ of Corti. Similar results were obtained in culture work on explants of developing (Zheng and Gao, 2000) and mature organ of Corti (Shou *et al.*, 2003). Together, these studies have shown that the nonsensory cells in the deaf ear retain the competence to respond to developmental genes and to convert to new hair cells.

Electrophysiological thresholds of the deaf *Atoh1*-treated animals improved, but the morphology of the new hair cells often appeared abnormal, especially in the outer hair cell region (Izumikawa *et al.*, 2005). It is possible that combining the transdifferentiation step with forced cell proliferation in the organ of Corti or its vicinity will yield better morphological and physiological restoration of the tissue. To advance such therapies toward clinical applications, it will be necessary to test and optimize efficiency and safety and to determine the ability of this approach to accomplish regeneration in ears that have been deafened for a long time.

#### IV. AUDITORY NERVE SURVIVAL FOLLOWING DEAFNESS

Profound deafness is usually associated with a loss of inner hair cells, the sensory cells responsible for transduction and activation of the auditory nerve. If there is loss of inner hair cells, a series of pathophysiological changes follow, including scar formation, a loss of the peripheral processes of the auditory nerve, and, over time, a substantial loss of the auditory nerve itself. This loss of auditory nerve is related to the loss of survival/maintenance factors, including the deafferentation-associated loss of neural activity and the loss of neurotrophic factors that had been released by hair cells and other cochlear elements lost during the scar process. Loss of these survival/maintenance factors causes these auditory neurons to enter into the cell death cycle.

Cochlear prostheses depend on direct stimulation of the auditory nerve, so auditory nerve survival is of major importance. The auditory nerve loss can be blocked or reduced either by blocking the cell death pathway or by replacing the survival/maintenance factors. Thus, activity can be replaced by direct cochlear electrical stimulation

with a cochlear prosthesis, and auditory nerve survival is enhanced (Lousteau, 1987; Hartshorn *et al.*, 1991; J. M. Miller *et al.*, 1995; Mitchell *et al.*, 1997; Leake *et al.*, 1991, 1992, 1995). Stimulation may serve as a survival factor through activation of voltage-gated ion channels and/or through up-regulation of autocrine factors, including neurotrophic factors. Neurotrophic factors can be infused into the cochlear fluids, to replace those that are lost, which is even more effective than electrical stimulation in enhancing auditory nerve survival following deafness (Ernfors *et al.*, 1996; J. M. Miller *et al.*, 1997; A. M. Miller *et al.*, 1999; Staecker *et al.*, 1996; Ylikoski *et al.*, 1998). The combination of electrical stimulation and application of neurotrophic factors is more effective than when either is applied singly (Kanzaki *et al.*, 2002; Shepherd *et al.*, 2005).

There is also interest in inducing regrowth of peripheral processes of the auditory nerve. Cochlear prostheses might have reduced thresholds if their target is closer, making them more energy efficient and reducing battery requirements. If regrowth can be directed toward specific sites on the cochlear prostheses, this might also allow a greater number of channels to be used, resulting in more and better frequency separation. Studies have now shown that infusion of neurotrophic factors BDNF, NT-3, and FGF can induce regrowth of the peripheral process of the auditory nerve that regresses following inner hair cell loss (Wise *et al.*, 2005; Altschuler *et al.*, 1999). Thus, neurotrophic factors can serve not only to enhance survival of the auditory nerve but also to restore its peripheral processes, although different factors may be necessary for most effective treatment(s). Directed regrowth remains a challenge.

## V. GENETIC DEAFNESS

One in 1000 newborns suffers from hearing impairment. In developed countries, more than half of the afflicted babies are deaf for genetic reasons. Genetic inner ear impairments can be nonsyndromic, affecting only hearing, or syndromic, with multiple defects occurring in several body systems. Many of the genes for deafness, as well as their products, have now been identified. Some of the affected proteins of the inner ear include cytoskeletal proteins such as myosin and a tectorial membrane protein (reviewed by Probst and Camper, 1999). Identification of the genes that are mutated in families with genetic inner ear impairments is important not only for diagnostic purposes, but also for the potential for prevention and cure. For example, Probst *et al.* (1999) identified a mutation in *Myo-15* as the cause for deafness and balance impairments in the shaker 2 deafness mouse. This mouse is a model for several families in which mutations in the very same gene cause genetic inner ear impairments (A. Wang *et al.*, 1998). Probst *et al.* (1998) demonstrated that in transgenic mice destined (genetically) to become deaf, insertion of the wild-type (correct) gene sequence into the fertilized egg corrected the genetic deficit, leading to normal inner ear structure and

function in the adult mouse. This demonstrated that addition of the correct copy of the gene can rescue the inner ear from genetic deficits. To make such interventions viable for clinical applications, it is necessary to develop the means for delivering genes into the inner ear cells that are affected directly by the mutations.

## VI. METHODS OF THERAPEUTIC INTERVENTION

With effective treatments for protection from acquired deafness and treatment following deafness identified, the next challenge is developing the methods for providing these interventions.

### Cochlear Prostheses

Auditory prostheses can provide direct stimulation of the auditory pathways for return of hearing following deafness. In severe and profound sensorineural hearing loss, the sensory cells of the cochlea are destroyed. Cochlear prostheses bypass the damaged receptor epithelium and electrically excite the auditory nerve directly. The development of the cochlear prosthesis has been the success story of the field of neuroprostheses. It has provided a therapy for the profoundly deaf, where none previously existed. The first FDA-approved inner ear implants, approximately 25 years ago, were single-channel devices that provided crude input and were an aid to lip reading. Now multichannel devices, combined with many advances in signal-processing strategies, routinely provide intelligible speech perception (e.g., Rauschecker and Shannon, 2002; Skinner *et al.*, 2002) with open set speech discrimination and even use of the telephone in the majority of implant recipients. With the success of cochlear implant performance and the low risk associated with its placement, the age at which implantation is considered has decreased to where very young children receive implants and show benefit from early placements, taking advantage of critical periods for auditory system development. There is also increasing bilateral placement to allow binaural hearing, important for spatial localization (Laszig *et al.*, 2004; Van Hoesel *et al.*, 2002; Verschuur *et al.*, 2005), with the benefit also greatest for early implantation during or preceding critical periods (e.g., Litovsky *et al.*, 2006). Even with later placements, there is still some induced maturation of pathways and improvement in performance (e.g., Gordon *et al.*, 2003).

### Central Auditory Prostheses

Central auditory prostheses can be advantageous when the cochlea is not suitable for implantation, when there is insufficient auditory nerve survival, or when auditory nerve must be removed in patients with VIII nerve tumors (acoustic neuroma). While a peripheral cochlear implant allows for more normal auditory pathway processing, the central implants can take advantage of the tonotopic organization of auditory nuclei for frequency separation. Central audi-

tory prostheses can also have reduced thresholds because of the proximity to neurons as well and increased dynamic range. Cochlear nucleus implants have been successfully applied in many subjects, with excellent performance recently reported (Lenarz *et al.*, 2002, 2004; Otto *et al.*, 2002; Colletti and Shannon, 2005) in nontumor patients; when there is a tumor (the most frequent need for central auditory prostheses), the complications of the tumor and its removal can compromise the long-term function of the cochlear nucleus implant (e.g., Otto *et al.*, 2002; Schwartz *et al.*, 2003). Auditory prostheses are therefore being developed for the inferior colliculus (Lenarz *et al.*, 2005) and in animal models show improved thresholds, increased dynamic range, and better frequency discrimination than cochlear implants (Lenarz *et al.*, 2006; Lim and Anderson, 2003, 2006, 2007).

### Gene Therapy

Gene therapy is used to manipulate levels of specific proteins in cells and tissues. It can be used to inactivate specific proteins or to overexpress them. In most cases, this is accomplished by introducing a foreign gene into these cells. Viral vectors are the most efficient vehicles for gene transfer. Adenovirus, herpes simplex virus, adeno-associated virus, and lentivirus can mediate gene transfer into cells of the inner ear (Patel *et al.*, 2004; Lalwani and Mhatre, 2003; Crumling and Raphael, 2006). When mature mammalian inner ears are inoculated with adenoviral vectors, fibroblasts and other cells of connective tissue origin are transduced with the highest efficiency (Raphael *et al.*, 1996; Yagi *et al.*, 1999). At present this limits the applicability of adenovirus-based gene therapy in the inner ear to genes encoding secreted and diffusible proteins, such as the neurotrophins. Overexpression of the human GDNF transgene with an adenovirus vector has been shown to protect hair cells from noise and ototoxic drug insults in guinea pigs (Yagi *et al.*, 1999). Similar treatment was also efficient in protecting spiral ganglion neurons from degeneration following hair cell loss (Yagi *et al.*, 2000). Several viral vectors have been shown to bestow protection on hair cells and spiral ganglion neurons by inserting transgenes encoding for neurotrophic factors and antioxidant genes (Cooper *et al.*, 2006; Kawamoto *et al.*, 2004; Nakaizumi *et al.*, 2004; Bowers *et al.*, 2002; X. Chen *et al.*, 2001; Staecker *et al.*, 1998).

### Biopolymers and Scaffolding

Biopolymers can be synthesized that contain both the protein sequence for silk, to provide strength and flexibility, along with sequences of functional domains that naturally occur in the extracellular matrix protein to confer specific biological properties (Cappello, 1990; Cappello *et al.*, 1990). These can be spun in microstructured thin films on the surface of prosthetic devices. Biopolymers can be produced that contain the sequence of fibronectin or laminin to provide a biological glue (for neurons and epidermal cells, respectively), which can then be coated on implants. This

can, in turn, be used to influence and stabilize the neuroprobe–tissue interface or to attach transformed cells for *ex vivo* gene transfer (see later). The biopolymer can also be used for timed release of specific factors. Thus a prosthesis could be providing electrical stimulation while releasing one or more chemical factors through microchannels (see later) and other factors through diffusion out of the biopolymer. Specific placement of biopolymer and microchannels can also provide different factors to different regions.

### Microcannulation – Miniosmotic Pumps

The fluid spaces of the cochlea provide for a closed environment well suited to receive local delivery of chemicals. Local delivery provides improved access and avoids the side effects that systemic delivery could entail. The technique of miniosmotic pumps with cannula into the inner ear fluid of scala tympani or into the middle ear with access through the round window has been developed in animals (e.g., Brown *et al.*, 1993; Prieskorn and Miller, 2000; Park *et al.*, 1998) and effectively utilized for local application of chemicals that provide protection from acquired deafness or enhanced survival of auditory nerve (see earlier sections). While devices for fluid delivery to the inner ear can be developed for human application (Schwab *et al.*, 2004; Hoffer *et al.*, 2001; DeCicco *et al.*, 1998), most recent efforts have focused on combining fluid delivery with cochlear prostheses (see next section).

### Combinations: Prostheses with Microchannels

Studies now show that combining electrical stimulation and chemical delivery is more effective in enhancing auditory nerve survival following deafness than either applied by itself (Kanzaki *et al.*, 2002; Shepherd *et al.*, 2005). Moreover, more patients with some residual hearing have been shown to benefit from cochlear implants and more patients with surviving hair cells are now considered candidates for cochlear implants. These subjects would benefit from protection of these remaining hair cells from the trauma of cochlear prosthesis insertion. There is also the potential of inducing regrowth of peripheral processes toward the stimulation sites, which could lower thresholds and enhance selectivity and separation. Therefore recent efforts have been made by cochlear implant manufacturers and research groups to develop cochlear prostheses capable of both electrical stimulation of the auditory nerve and delivery of pharmaceuticals into the cochlear fluids (Altschuler *et al.*, 2005). These have been successfully applied in animal studies (Shepherd *et al.*, 2005), and clinical application is beginning.

### Polymer Coatings for Cochlear Electrodes

There is considerable interest in the development of polymer coatings that could improve the long-term performance of cochlear implants. By lowering the impedance of the electrode, this would reduce energy requirements and increase battery life. Also, the ability to attract the neurons

closer to the electrode surface, or to bring the electrodes closer to the spiral ganglion neurons by growing conducting polymer filaments out from the electrode itself, should improve the ability to target individual neuronal populations. Recent work shows the potential for improving the sensitivity, selectivity, and lifetime of cochlear implants.

Conducting polymers such as polypyrrole (PPy) have been used to make electrically active coatings on biomedical devices (Schmidt, Shastri, Vacanti, and Langer, 1997). It has been found that electrochemically deposited coatings of polypyrrole can significantly reduce the impedance of electrodes, particularly at the 1 kHz frequency of interest for neural recording (Cui, Hetke, Wiler, Anderson, and Martin, 2001) (George *et al.*, 2005). One issue with PPy is that it is relatively unstable in a biological environment, due presumably to coupling defects in the chemistry along the backbone. The diethoxy-functionalized thiophene poly(3,4-ethylene dioxothiophene) (PEDOT) has shown to be much more stable, and is also able to readily deposited on conducting electrodes (Cui and Martin, 2003). PEDOT films can be tailored into a wide variety of geometries including porous templates with variable pore size (Yang and Martin, 2004b; Yang and Martin, 2004a) nanotubes (Abidian and Martin, 2006), and nanofibrils (Yang, Lipkin, and Martin, 2007).

PPy and PEDOT can also be used to incorporate and deliver pharmacological agents. It has been shown that bioactive molecules can be realized from the conducting polymers using an external bias (Pernault and Reynolds, 2000) (George *et al.*, 2006). Neurotrophins such as NGF (Kim, Richardson-Burns, Hendricks, Sequera, and Martin, 2006) (Gomez and Schmidt, 2007) and NT-3 (Richardson *et al.*, 2007) have been incorporated into PPy and PEDOT, and have shown to enhance neurite regrowth. Nanotubes of conducting polymers can be formed around filaments of degradable polymers such as PLGA containing anti-inflammatory agents or neurotrophins (Abidian and Martin, 2006).

Cochlear implants can also be coated with hydrogels, in order to provide attachments sites for cells, to provide a means for drug delivery, and for the delivery of genetically-transfected cells. These gels can also be used as matrices for polymerization of conducting polymer (Kim, Abidian, and Martin, 2004), and they provide a means for drug delivery from degradable nanoparticles (Kim and Martin, 2006). One useful strategy is likely to be the use of hydrogels loaded with cells transfected to deliver BDNF (Nakaizumi, Kawamoto, Minoda, and Raphael, 2004).

Recently it has been demonstrated that PEDOT can be directly grown in living tissue (Richardson-Burns, Hendricks, and Martin, 2007). Efforts are now actively underway to polymerize conducting polymers directly in the cochlea itself, with the intention of creating a more intimate, stable contact between the electrode and the spiral ganglion cells.

This could be part of a hybrid coating that also delivers neurotrophins, anti-inflammatory agents, or transfected cells.

## Stem Cells

The use of stem cells, exogenous or endogenous, provides the potential to treat deafness by replacing lost hair cells or lost auditory nerve. Embryonic stem cells or stem cells derived from bone marrow can be induced to reach a hair cell-like phenotype (Li *et al.*, 2003; Parker and Cotanche, 2004) or an auditory nerve-like phenotype (Kondo *et al.*, 2005) *in vitro*. *In vivo* studies have shown that mouse embryonic stem cells can be placed into the cochlear fluids of scala tympani or directly into the auditory nerve, survive, and differentiate into a neuronal phenotype (Okano *et al.*, 2005; Sakamoto *et al.*, 2004; Hu *et al.*, 2005; Hernandez *et al.*, 2006; Hildebrand *et al.*, 2005). Stem cells that reach a neuronal phenotype will send processes that reinnervate hair cells (Martinez-Monedero *et al.*, 2006; Matsumoto *et al.*, 2005) or integrate with auditory nerve processes. We found that differentiation into an auditory nerve-like phenotype typical of SGN was improved by applying factors that guide auditory nerve differentiation during normal development. The cochlear fluid compartments provide a means for applying factors *in vivo*. We used mouse embryonic stem cells with Ngn1, a proneural gene associated with auditory nerve fate determination, under control of a doxycycline-inducible promoter. We then induced transient *in vivo* expression of Neurogenin 1 and followed this with intrascalar infusion of growth factors GDNF and BDNF. We found increased numbers of stem cells reaching a glutamatergic phenotype and that these differentiated stem cells gave off processes that integrated with the remaining auditory nerve (Hernandez *et al.*, 2006).

Another exciting development is the finding that there are endogenous pluripotent cells that can be gathered from human (Rask-Andersen *et al.*, 2005) or animal (Rask-Andersen *et al.*, 2005; Zhai *et al.*, 2005) cochlea or vestibule (Li *et al.*, 2003). This provides the potential that these cells can be cultured and placed into the cochlea to replace hair cells or auditory nerve, or perhaps they can be induced to differentiate *in vivo* to provide replacement.

## VII. CONCLUSIONS

Major advances in our understanding of the molecular mechanisms underlying deafness and of the factors that influence and modulate its expression and progression have occurred since the mid-1990s. We can expect, as progress in these areas continues, that this knowledge will form the basis for *molecular otology*. Novel tissue engineering-based therapeutic interventions may become a major part of the practice of otolaryngology in the 21st century.

# Chapter Sixty-Seven

## Stem Cells in the Eye

*Michael E. Boulton, Julie Albon, and Maria B. Grant*

- I. Introduction
- II. Corneal Epithelial Stem Cells
- III. Retinal Progenitor Cells
- IV. Bone Marrow Stem Cells

- V. Potential for Stem Cells in Ocular Repair and Tissue Engineering
- VI. References

### I. INTRODUCTION

The eye is a complex organ consisting of epithelial, mesenchymal, connective, and neural tissue. Vision is dependent on carefully regulated structural and functional integration of these tissues. Since the early 1980s it has become increasingly apparent that there are a number of stem cell niches in ocular tissues that are important in maintenance and repair. This chapter considers our current knowledge of ocular stem cells and reflects on their therapeutic potential in repairing damage to ocular tissue.

### II. CORNEAL EPITHELIAL STEM CELLS

Limbal stem cells (LSCs) are crucial to corneal epithelial tissue repair and regeneration throughout the life of the adult cornea (see Dua and Azuaro-Blanco, 2000a; Kinoshita *et al.*, 2001; Boulton and Albon, 2004). The ability of LSCs to self-renew and generate daughter cells that undergo progressive differentiation until they are shed from the surface as terminally differentiated cells supports the concept of “stemness” in the cornea.

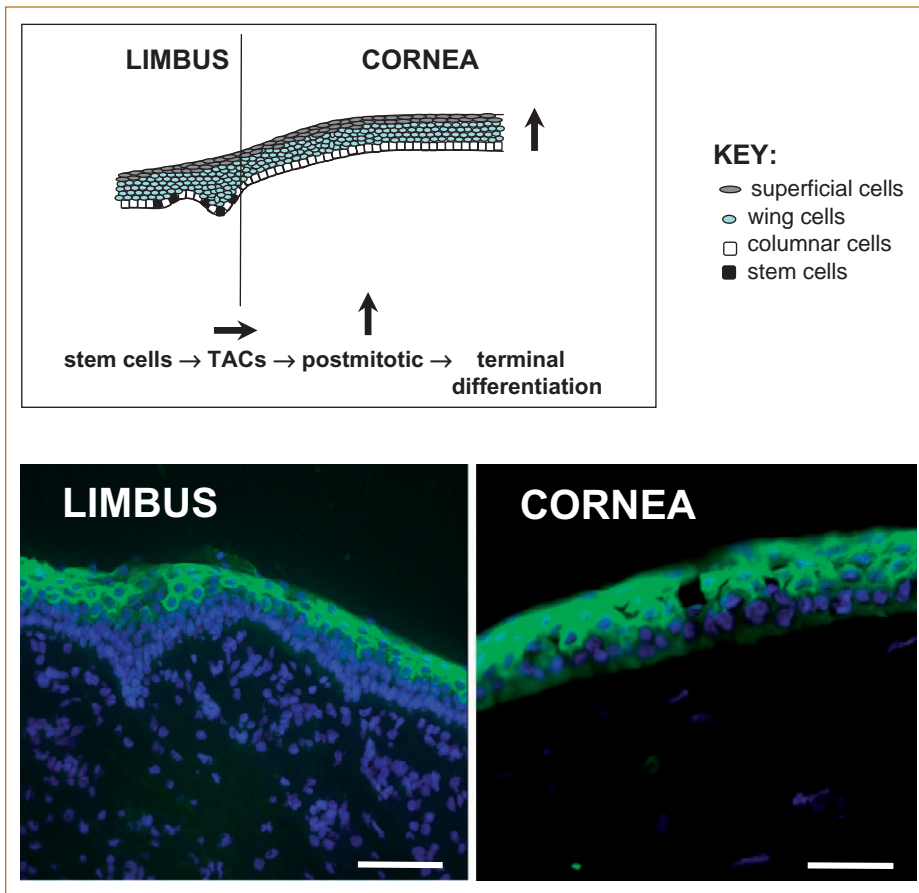

The corneal epithelium is the outermost layer of the cornea, whose functions include transparency, refraction, and protection. It consists of a stratified, multilayered (five to seven layers) epithelium that is continually renewed from a population of relatively undifferentiated cells that reside in the basal cell layer of the corneal limbus. The *limbus* is defined as a narrow ring of tissue situated between the

cornea and the conjunctiva, terminating anteriorly at Bowman’s membrane. The limbus, as is appropriate for all stem cell niches, offers both physical protection and nourishment to the stem cells that reside there. The deep undulations of the Palisades of Vogt ensure that the limbal stem cells are hidden and protected from any hostile external environment, while the nearby limbal blood vessels provide nourishment. In addition, melanin in LSCs is thought to protect against ultraviolet light and reactive oxygen species. LSCs are slow-cycling cells that self-renew and produce transient amplifying cells (TACs). The TACs differentiate into postmitotic cells as they move centripetally toward the central cornea and upward from the basal corneal epithelial cell layer, before being shed from the epithelial surface as terminally differentiated, flattened superficial cells (Fig. 67.1) (Beebe and Masters, 1996; Thoft, 1984).

Interestingly, a recent study by Dua *et al.* (2005) suggests that the limbal stem cell niche may extend beyond that originally thought. They termed this novel anatomical structure, which formed cords of ABCG2-positive epithelial cells extending from the limbal palisades, the *limbal epithelial crypt*. Further studies are required to determine the “stemness” of cells derived from this structure.

### The Limbal Stem Cell Niche

Evidence in support of the limbus as a niche for stem cells that renew the corneal epithelium has been described

**FIG. 67.1.** Diagram of the architecture of the corneal epithelium and limbus (upper panel). Cytokeratin localizes to all cell layers of the human corneal epithelium, but only in the supra-basal layers in the limbal epithelium (lower panels). Bar = 50  $\mu$ M.

in several studies. The migration of limbal pigmented cells toward the central cornea in a wound-healing response provided evidence for the existence of LSCs in the Palisades of Vogt (Davenger and Evenson, 1971). The fact that cells in the limbal niche are slow-cycling (Cotsarelis *et al.*, 1989), relatively undifferentiated cells (Schermer *et al.*, 1986; Chaloin-Dufau *et al.*, 1990) and, when cultured *in vitro*, have a higher proliferative potential than those of cultured central or peripheral corneal epithelial cells (Ebato *et al.*, 1998; Lindberg *et al.*, 1993; Pellegrini *et al.*, 1999) provided further evidence. The distribution of LSCs does not appear to be uniform; the population of LSCs differs according to region, with the greatest being in the superior and inferior cornea (Lauweryns *et al.*, 1993; Wiley, 1991). A single, unipotent LSC self-renews and produces a transient amplifying cell (TAC). The TACs proliferate to produce more TACs, dependent on requirement (e.g., proliferation will be increased during corneal regeneration following wounding) (Fig. 67.1). Each stem cell is capable of producing TACs throughout one's lifetime, but it is likely that a proportion of LSCs remain in the resting state of  $G_0$  for at least part of their lifetime (Becker *et al.*, 1965; Lajtha, 1979; Cotsarelis *et al.*, 1989). Following wounding, LSC proliferation rate can be up-regulated as much as eight-to ninefold (Cotsarelis *et al.*, 1989; Lehrer *et al.*, 1998; Chung *et al.*, 1992) within 12 hours, compared to

a twofold increase in TACs following central epithelial injury (Cotsarelis *et al.*, 1989). Epithelial cell proliferation rate is highest in the peripheral cornea, in comparison to both central cornea and limbus (Ebato *et al.*, 1998; Ladage *et al.*, 2001). The change in the frequency and number of TAC division represents a shortening of cell-cycle time triggered by cell injury and loss on wounding (Cotsarelis *et al.*, 1989; Lehrer *et al.*, 1998).

As for other stem cell niches, the adjacent stromal environment plays a critical role in defining stem cell destiny. The precise molecular mechanism by which the stromal niche regulates limbal stem cell fate is unclear, although it is likely due to intricate interactions between the stem cell and its microenvironment (Morrison *et al.*, 1997; Watt and Hogan, 2000) as well as short- and long-range signals.

### Differential Regulation of Limbal Stem Cells and TACs

The regulation of stem cell homeostasis typically involves various short- and long-range internal and external factors. The environments that encompass limbal stem cells and TACs differ in various ways and are important in determining cell fate in each region (Suda *et al.*, 2006; Wolosin, 2000). Important definers include the differences that exist

between the basal substrate that underlies these cells in the limbus and peripheral corneal peripheral cornea. Differences include distinct laminin isoforms, collagen IV  $\alpha$ -chains (Ljubimov *et al.*, 1995; Tuori *et al.*, 1996), and the basement membrane-related AE27 BM antigen (Kolega *et al.*, 1989).

Cytokines are well known to modulate both corneal epithelial and stromal wound-healing responses (Wilson *et al.*, 2001) through a number of mesenchymal–epithelial interactions (Li and Tseng, 1995; Carrington and Boulton, 2005; Carrington *et al.*, 2006). It is almost certain that they play similar roles in the regulation of LSCs and TACs. Depending on the mesenchymal–epithelial interaction in which they are involved, cytokines can be assigned to groups. Epithelial cells secrete type I cytokines (TGF $\beta$ , IL1 $\beta$ , PDGF-BB) to modulate fibroblasts; mediators of both epithelial and fibroblasts are type II cytokines (IGF1, TGF $\beta$ 1, TGF $\beta$ 2, bFGF); and corneal fibroblasts produce type III cytokines (KGF, HGF). Interplay between epithelial cells and stromal fibroblasts in the cornea and limbus is likely to influence cell behavior and phenotype (Li and Tseng, 1995; Li *et al.*, 1999; Wilson *et al.*, 1994; Carrington and Boulton, 2005; Carrington *et al.*, 2006). A good example is the presence of TGF $\beta$  1, 2, and 3 and receptors in the limbal epithelium. TGF $\beta$  inhibits LSC proliferation (Li *et al.*, 1999) and may therefore serve to influence stem cell maintenance in the limbus. Stem cell regulation by many cytokines/growth factors has been reviewed and reported by various investigators (Kruse and Volcker, 1997; Dua and Azuaro-Blanco, 2000a, 2000b; Daniels *et al.*, 2001; Kruse and Tseng, 1993; J. Imanishi *et al.*, 2000; Kruse, 1994). In addition we have recently shown that Notch/Jagged/Delta interactions play a key role in TAC differentiation (A. Ma *et al.*, 2007).

### Evidence of Corneal Epithelial Cell Plasticity

The plasticity of adult corneal epithelial cells is implied by their ability to alter phenotype in response to signals from the embryonic dermis (Ferraris *et al.*, 2000). These findings suggest that corneal epithelial cells can be reprogrammed. The screw model of stem cell behavior suggests that adult TACs, once differentiated and under certain signals, can be induced to revert to their original stemness (Loeffler and Potten, 1997; Potten and Loeffler, 1990). In the foregoing study, adult corneal epithelial cells appear to have matured (after dedifferentiation) into cells that express epidermal specific keratin 10. The corneal epithelial cells responded to signals and directions of their new environmental niche, such that their fate was redirected to allow participation in hair-follicle morphogenesis (Ferraris *et al.*, 2000; Pearton *et al.*, 2004). The mechanisms that control these processes are still to be determined.

The potential for epithelial cell differentiation into a neural cell phenotype has also been suggested. However, since the embryonic corneal epithelium is derived from the neural ectoderm, it is not surprising that a subset of epithelial

cells expresses the neural marker nestin (Seigel *et al.*, 2003) or that Notch 1 expression can be induced in cultured limbal epithelial cells (Zhao *et al.*, 2002).

### Pursuit of a Corneal Stem Cell Marker

General stem cell characteristics that are exhibited by corneal LSCs define their stem cell status. The slow-cycling nature of LSCs was first recognized by the detection of label-retaining cells in the basal cell layer of the limbus (Cotsarelis *et al.*, 1989). The lack of differentiation of a subset of cells within the basal cell layer of the corneal limbus adds to their potential as being stem cells. The relative undifferentiated status of LSCs has been demonstrated by the lack of the epithelial differentiation markers, 64-kDa cytokeratin 3 (CK3), (Schermer *et al.*, 1986), and the cornea-specific cytokeratin 12 (Chaloin-Dufau *et al.*, 1990; Kurpakus *et al.*, 1990; R. Wu *et al.*, 1994) in the limbal basal epithelium, compared to localization to all layers of the corneal and suprabasal cells of limbal epithelium (Fig. 67.1). In addition, limbal stem cells are small and round and have features suggestive of a more primitive phenotype (reviewed by Schlotzer-Schrehardt and Kruse, 2005).

The TACs are rapid-cycling cells, with limited proliferative activity, which, like stem cells, can be up-regulated in corneal wound healing. At the corneal margin, basal cells coexpress vimentin and cytokeratin 19 (Kasper, 1992; Lauweryns *et al.*, 1993), and as the TAC migrates across the limbocorneal margin, the cells express differentiation features: cytokeratin 3 and 12 (Kurpakus *et al.*, 1990; Schermer *et al.*, 1986; Wolosin *et al.*, 2000). Lavker *et al.* (1991) identified peak proliferative activity in this zone.

As with many tissues derived from stem cells, to date a definitive marker that characterizes the limbal stem cell has yet to be identified. However, a number of negative differentiation markers and putative stem cell–specific markers have been investigated and are comprehensively reviewed by Wolosin *et al.* (2004) and Schlotzer-Schrehardt and Kruse (2005). Table 67.1 lists some of the markers described that may be used to discriminate basal limbal epithelial cells from basal corneal epithelial cells. Used in combination, these markers have potential in limbal stem cell isolation and in the characterization of the differentiation state.

**Table 67.1.** Positive and negative markers of limbal basal epithelial cells

Negative markers of LSCs	Limbal basal cell markers
K12/K3	ABCG2
Connexin 43	K19
P-cadherin	Vimentin
Involucrin	Integrin $\alpha$ 9
Integrins $\alpha$ 2, $\alpha$ 6, $\beta$ 4	KGF-R
Nestin	Metallothionein

A number of putative stem cell markers have been suggested, but most are not solely expressed in a subpopulation of cells in the basal cell layer of the limbus or are highly expressed in the limbal basal epithelium (i.e., positive for corneal basal cells also). Alpha-enolase is present in basal cells of the embryonic cornea (Chung *et al.*, 1992) and was observed in basal limbal epithelial cells (Zieske, 1994; Zieske *et al.*, 1992). However, its potential as a stem cell marker was unlikely, for alpha-enolase is expressed in basal cells (nonstem cells) of several stratified epithelia and was also detected in basal cells of the peripheral cornea. Pellegrini *et al.* (2001) indicated the transcription factor p63 as a potential keratinocyte stem cell marker. However, p63 did not appear to be exclusive to corneal stem cells, for low levels were occasionally observed in peripheral corneal basal cells. Also, p63 was identified at low levels in mero-clones (young TACs) as compared to holoclones (stem cells) (Pellegrini *et al.*, 2001).

Epithelial tissues are suggested to consist of around 0.4% adult stem cells. In the limbus, estimations for the stem cell population that maintains the corneal epithelium indicate less than 10% of the basal limbal epithelial cell population (Lavker *et al.*, 1991), or 100 cells, in the rodent cornea (Collinson *et al.*, 2002). Like other stem cells, a subpopulation (known as side-population cells) of limbal epithelial cells, approximately 0.4%, are able to efflux Hoechst 33342, a property attributable to the ATP-binding cassette transporter G2 (Watanabe *et al.*, 2004; Wolosin *et al.*, 2004; de Paiva *et al.*, 2005; Umemoto *et al.*, 2006). Interestingly, de Paiva *et al.* (2005) and Umemoto *et al.* (2006) demonstrated conflicting results in the potential of side-population cells to proliferate and form colonies *in vitro*. Umemoto *et al.* (2006) reported that the discrepancy in findings was due to the non-colony-forming side-population cells being arrested in G0/G1, having no telomerase activity and thus representing a quiescent stem cell population in the basal cell layer of the limbus. A study of rabbit limbal epithelial side-population (SP) cells concurred: the SP cells represented 0.73% of the population, were small, undifferentiated, and noncycling, and could be induced to enter the cell cycle on wounding (Park *et al.*, 2006).

### Potential for Tissue Engineering of Limbal Stem Cells in Ocular Surface Disease

In corneal pathologies such as traumatic injuries (chemical and thermal burns), contact lens-induced keratopathy, Stevens Johnson syndrome, and ocular pemphigoid (Chiou *et al.*, 1998; Wagoner, 1997), the absence or depletion of LSCs results in failure of corneal epithelial formation. Instead, persistent epithelial defects, neovascularization, scarring, ulceration, and in some instances corneal perforation result. In such cases, corneal transplantation that involves full-thickness transplant of a central corneal button (without inclusion of the limbal region) will not restore vision.

Several investigators have harnessed the proliferative potential of corneal and limbal epithelial cells for therapeutic purposes (Pellegrini *et al.*, 1997, 1999; Kruse and Tseng, 1993; Koizumi *et al.*, 2001a, 2001b). Limbal epithelial cells have a higher proliferative potential than cells in the peripheral and central cornea, and clonogenicity studies have confirmed that holoclones (derived from stem cells) have the greater capacity for clonal expansion than meroclones or paraclones (Pellegrini *et al.*, 1999). Clinically, cells derived from this region have led to successful limbal transplantation, with the formation of a stratified corneal epithelium (Dua and Azuaro-Blanco, 2000b; Koizumi *et al.*, 2001a, 2001b). In the absence of the limbal epithelium, conjunctivalization of the cornea results in an abnormal corneal surface (Huang and Tseng, 1991; Kruse *et al.*, 1990).

Initially, autologous conjunctival transplantation was performed to treat limbal deficiency-related ocular surface disease (Thoft, 1977; Herman *et al.*, 1983; Clinch *et al.*, 1992). However, since the discovery that “conjunctival transdifferentiation” does not occur (Dua, 1998; Kruse *et al.*, 1990; W. Chen *et al.*, 2003), other methods were investigated. Keratoepithelioplasty describes the transplant of lenticules of peripheral cornea (Thoft, 1984), and in 1989 the first human conjunctival limbal autograft was performed (Kenyon and Tseng, 1989). Kinoshita *et al.* (1991) then introduced the concept of transplantation of limbal stem cells in rabbits. Human limbal stem cell autografts utilize the limbal cells of the healthy contralateral eye, whereas bilateral disorders necessitate stem cell allografts isolated from living tissue-matched eyes or nonmatched cadaver eyes.

Next, the field progressed to *ex vivo* expansion of limbal stem cells. This approach minimized the risk of limbal stem cell deficiency in the donor eye (J. J. Chen and Tseng, 1990), since only a small biopsy was required and allograft rejection was reduced due to the elimination of Langerhan cells during culture (Lavker *et al.*, 2004). Pellegrini *et al.* (1997) reported the first successful autologous graft for unilateral severe ocular surface disease, using cultivated corneal epithelial stem cells. A number of substrates for the culture of epithelial stem cells have been introduced, including fibrin, amniotic membrane, and thermoresponsive plastic. The latter allows cultivated epithelial cells to be released on change of temperature so that only the epithelial sheets are transplanted (Nishida *et al.*, 2004a). The fibrin gel, used by Rama *et al.* (2001) as a carrier, is degraded following transplant, whereas the amniotic membrane appears to persist following transplantation (Connon *et al.*, 2006).

Preserved amniotic membrane has been used for several years in combination with limbal transplantation to promote ocular surface reconstruction in patients suffering from severe ocular-surface disease. The benefits of transplanting amniotic membrane in transplantation include provision of growth factors important in reepithelialization, antiinflammatory effects, inhibition of conjunctival fibrosis (Kinoshita *et al.*, 2004), and antibacterial properties. It is also postu-

lated that the amniotic membrane (AM) provides the limbal stem cells with a new niche (Gruetrich *et al.*, 2003). A number of studies have evaluated the use of intact AM versus denuded AM (epithelial cells removed) as a substrate for limbal stem cell culture (Tsai *et al.*, 2000; Schwab *et al.*, 2000; Koizumi *et al.*, 2002). Limbal epithelial cells have been shown to demonstrate stem-like properties when cultured on intact AM, including slow cycling and lack of expression of the differentiation markers CK3, CK12, and connexin 43 (Gruetrich *et al.*, 2003). However, cultivation on a denuded AM showed increased limbal epithelial cell migration and produced a better-stratified epithelium (Koizumi *et al.*, 2002). If denuded AM is used to cultivate epithelial cells, growth-arrested 3T3 feeder layers are required to synthesize the growth factors that were previously produced by AM epithelial cells.

Bioengineered epithelial tissue equivalents have been derived from both limbal explants and cell suspensions isolated from limbal epithelium (Koizumi *et al.*, 2002). Both techniques generate epithelial cell sheets that express CK3 and CK12, although more evident in superficial cells of the cell suspension-derived sheets. The latter also resulted in the formation of a greater number of desmosomes, smaller basal intercellular spaces, and secure attachment via hemidesmosomes to the underlying basement membrane. The use of the air-interface method of culture, whereby the level of media is reduced to below the epithelial cell surface, ensures that a well-differentiated, stratified epithelial tissue is available for transplantation.

*Ex vivo* expanded cells have been used, in both allografts and autografts, to promote repopulation of the recipient cornea by donor-derived cells to facilitate restoration of epithelial integrity and vision (Tsai *et al.*, 2000; Tseng *et al.*, 1998; Tsubota *et al.*, 1999; Schwab *et al.*, 2000; Koizumi *et al.*, 2001a, 2001b). In the case of allografts, immunosuppression is required to prevent epithelial rejection.

Donor epithelial cells have been identified in the recipient bed for up to 30 months after limbal allograft transplantation (Shimazaki *et al.*, 2001), but the long-term duration of donor-derived epithelial stem cell viability remains uncertain (Shimazaki *et al.*, 2001; Williams *et al.*, 1995; Swift *et al.*, 1996). Although successful long-term clinical outcome has been described in limbal allografts, donor epithelial-cell survival could not be detected (Henderson *et al.*, 2001). Whether donor limbal stem cell survival is sustained or activation of resident recipient stem cells occurs on reestablishment of niche signals has yet to be confirmed.

### Tissue-Engineered Stem Cells from Other Tissues as an Alternative to Limbal Epithelial Cells

#### Oral Mucosa

Nakamura *et al.* (2003) pioneered the idea of using *ex vivo* expanded oral mucosal cells in autologous grafts to reconstruct the corneal epithelium of a rabbit. As with

limbal epithelial cells cultured *ex vivo*, oral epithelial cells were enzymatically isolated from oral mucosal biopsies and cultured on denuded AM using the air-lift culture system. The epithelial tissue equivalent, which was generated after two to three weeks culture, showed cornea-like properties with expression of CK3 (but not CK12) and the formation of a five- to six-layered stratified epithelium with desmosomes, hemidesmosomes, and tight junctions. Subsequently, the feasibility of using oral mucosa to treat corneal epithelial pathology in humans has been confirmed (Nishida *et al.*, 2004b; Nakamura *et al.*, 2004; Inatomi *et al.*, 2006).

#### Bone Marrow Stem Cells (BMSCs)

Bone marrow-derived CD34<sup>+</sup> progenitor cells have been identified in the cornea, particularly in the stroma (Nakamura *et al.*, 2005). This suggests that BMSCs may play a role in stromal maintenance and repair. Transplantation of bone marrow-derived human mesenchymal stem cells (cultivated on human amniotic membrane) onto the ocular surface of a chemically damaged rat cornea demonstrated a novel idea for therapeutic reconstruction of the ocular surface. However, it appeared that the mesenchymal stem cells did not differentiate into corneal epithelial cells, but served to suppress inflammation and angiogenesis (Y. Ma *et al.*, 2006).

### The Bioengineered Cornea

The idea of a bioengineered cornea has arisen, with corneal equivalents being reconstructed from corneal cell lines. Griffith *et al.* (1999) reconstructed a human cornea from immortalized cells. The resultant corneal equivalent behaved similarly to a normal cornea with respect to morphology, transparency, ion and fluid transport, and gene expression. However, bioengineering for the production of a replacement implant for wounded or diseased human corneas is still at the investigatory stage and requires further development in order to produce a bioimplant with the same tensile strength, curvature and durability as a normal cornea. Perhaps using LSCs, BMSCs or combinations thereof in the future will overcome some of these problems and obviate the need for immortalized cell lines. The ideal artificial implant is likely to be a composite of biomaterials and cells, to provide a transparent, flexible, but strong biocompatible implant that can withstand surgical procedures as well as normal day-to-day mechanical stresses. To this purpose the chemically cross-linked collagen-glycosaminoglycan biomatrix (Pieper *et al.*, 2002) and naturally occurring biomaterials (e.g., coral or sponges) have been suggested.

### Stem Cells in the Corneal Endothelium and Conjunctival Epithelium

While the first part of this chapter concentrated on LSCs, there is evidence for other stem cell populations in the anterior segment of the eye. The conjunctival epithelium,

**FIG. 67.2.** Immunofluorescent localization of HSC-derived  $\text{gfp}^+$  cells. All images were taken from chimeric animals whose bone marrow had been ablated by irradiation and then reconstituted with HSC from  $\text{gfp}$  homozygous donor mice. In panels **A** (z-projection of a confocal stack) and **B** (epifluorescence fluoromicrograph), the eyes of chimeric animals were first injected with a recombinant viral vector expressing VEGF, after which branch retinal vessel occlusion was performed by laser photocoagulation. The resulting combination of growth factor overexpression and ischemic injury leads to the recruitment and incorporation of bone marrow–derived endothelial progenitor cells to areas of vascular injury in the neural retina. The red fluorescence results from binding of rhodamine-conjugated *R. communis* agglutinin binding specifically to mature endothelial cells. Note the  $\text{gfp}^+$  cells in these panels colocalizing with the vascular walls. The chimeric mouse in panel **C** had its RPE damaged by intraperitoneal injection of  $\text{NaIO}_3$ . Red fluorescence in this panel results from an antibody to RPE65, found only on the surface of mature RPE cells. Green fluorescence again results from  $\text{gfp}$  expression. Note that the colocalization of these markers (orange-yellow), along with the hexagonal morphology, indicates that damaged RPE can be repaired by recruitment and differentiation of bone marrow–derived cells. Finally, the chimeric animal in panel **D** was subjected to laser rupture of Bruch's membrane to induce choroidal neovascularization. Within the choroidal vascular lesion, astrocytes are identified by red fluorescence via antibody to S100 $\beta$ , vascular cells by blue fluorescence through *G. simplicifolia* isolectin B4, and bone marrow–derived cells by  $\text{gfp}$ . Note the  $\text{gfp}^+$  cellular processes emanating from astrocytes, especially center right. Panels **A**, **B**, and **D** are 40 $\times$  original magnification. Panel **C** originally 60 $\times$  magnification. Images in panels **A** and **B** courtesy of Nilanjana Sengupta and Sergio Caballero, Pharmacology and Therapeutics, University of Florida, Gainesville, FL; images in panels **C** and **D** courtesy of Tailoi Can-Ling, Dept. of Anatomy, University of Sydney, Sydney, NSW, Australia.

like the corneal epithelium, undergoes constant renewal. The source of the population of stem cells is controversial, with different reports localizing stem cells to the fornix, palpebral, and mucocutaneous zones. Evidence demonstrating slow-cycling cells with higher proliferative capacity in these regions (Wei *et al.*, 1995; Wirstschafter *et al.*, 1999; W. Chen *et al.*, 2003), together with clinical observations, supports this concept. Unlike the stem cells of the corneal epithelium, conjunctival stem cells are not unipo-

tent; they differentiate into either a mucin-secreting goblet cell or an epithelial cell. Wolosin *et al.* (2004) suggests that the different epithelial phenotypes of the conjunctiva and cornea are under the control of genes present in only one of the two epithelia. In addition, Whitehart *et al.* (2005) proposed the existence of a stem cell niche in the posterior limbus, between the endothelium and trabecular meshwork that supplies both trabecular meshwork and corneal endothelium. Furthermore, Kawasaki *et al.* (2006) have described

clusters of corneal epithelial cells residing ectopically in human conjunctival epithelium.

### III. RETINAL PROGENITOR CELLS

It has been extensively reported that stem cells exist in the retina of fish and amphibians and that these cells add to the retina throughout their lifetime (Perron and Harris, 2000). Furthermore, these cells, which are located to the ciliary-retinal interface, are also able to regenerate a complete retina, including retinal pigment epithelium (RPE), under appropriate experimental conditions (Reh and Levine, 1998). By contrast, the neural retina and RPE in mammals are largely developed by the early postnatal period and show no evidence of adult regeneration as observed in fish and amphibians (Perron and Harris, 2000; Fisher and Reh, 2003).

Surprisingly, retinal progenitor cells were not identified in mammals such as mouse, rat, cow, and human until 2000 (Tropepe *et al.*, 2000; Ahmad *et al.*, 2000). These retinal progenitor cells, which are located at the ciliary marginal zone, represent only about 0.2% of pigmented cells in the ciliary margin. These progenitors display many of the properties associated with stem cells: (1) They are multipotential, (2) they can self-renew, and (3) they are proliferative and express the neuroectodermal marker nestin. Other potential markers can include CD133, CD15, Notch, Numb, and FGFR4 (see Young, 2005). These retinal progenitor cells can clonally proliferate *in vitro* to form sphere colonies of cells that exhibit differentiation markers for a variety of cell types, including photoreceptors, intermediate neurons, and Muller glia (Tropepe *et al.*, 2000; Layer *et al.*, 2001). Thus it would appear that these progenitors have the potential, given the right environment, to be engineered into the morphological and functional layers associated with the retina.

The inability of these ciliary-margin progenitor cells to renew retinal cells in the postnatal period in mammals indicates that the progenitor cells find themselves in an inhibitory environment. Little is known about what regulates retinal progenitor cells, but transcription factors such as Pax6, Six3, Rx1, Chx10, and Hes1 (Tropepe *et al.*, 2000; Marquardt and Gruss, 2002) are strongly implicated, as is the cyclin-dependent kinase inhibitor protein, p27<sup>Kip1</sup> (Levine *et al.*, 2000). Growth factors such as FGF2, EGF, and IGF-I have all been reported to regulate proliferation, but their precise role remains equivocal (Tropepe *et al.*, 2000; Ahmad *et al.*, 2000; Fisher and Reh, 2003; Levine *et al.*, 2000). Furthermore, it appears from studies in the chick that Muller glia have the potential to become neurogenic retinal progenitor cells. Furthermore, Muller glia cells appear to play an important role in the generation of multipotent precursor cells from embryonic retinal cells (Layer *et al.*, 2001).

The identification of adult retinal progenitor cells opens the possibility that these cells can, given the appropriate cues, be engineered for transplantation in retinal degenerations such as retinitis pigmentosa and age-related macular

degeneration (Ali and Sowden, 2003). Due to the limited number of retinal progenitor cells and the difficulty of isolating them, investigators have concentrated on investigating the incorporation and differentiation in the retina of transplanted brain-derived neural progenitor cells (Akita *et al.*, 2002; Sakaguchi *et al.*, 2003; Guo *et al.*, 2003), embryonic retinal progenitor cells (Yang *et al.*, 2002), bone marrow-derived stem cells (Tomita *et al.*, 2000), and embryonic stem cells from the inner mass of the mouse blastocyst (Schraermeyer *et al.*, 2001). While these studies, largely carried out in rodents, provide proof of principle for stem cell transplantation, differentiation, and integration in the host retina, they do emphasize that the correct inductive cues are essential for a successful outcome. Studies in the pig have shown that retinal progenitor cell xenografts to the pig retina can result in integration and differentiation (Warfvinge *et al.*, 2005). Furthermore, recent research has shown that retinal progenitor cells can be isolated and greatly expanded *ex vivo*. When grafted into the degenerating retina of dystrophic mice, a subset of retinal stem cells developed into mature neurons, including cells expressing photoreceptor markers (Klassen *et al.*, 2004; Young, 2005). Not only was rescue of photoreceptors observed, but there was also integration of donor cells, and animals showed improved light responsiveness. Despite these successes, cell delivery, survival of transplanted cells, and regulated differentiation of grafted cells need to be optimized if we are to regenerate a fully functional adult retina.

### IV. BONE MARROW STEM CELLS

Although not resident in the eye, it appears that bone marrow stem cells (BMSCs) play an important role in retinal homeostasis and repair. Adult BMSCs are mostly quiescent cells that comprise ~0.05–0.1% of the bone marrow (T. Imanishi *et al.*, 2004; Morrison *et al.*, 1995; Spangrude *et al.*, 1988). Adult hematopoietic stem cells (HSCs) expand and differentiate exclusively in the bone marrow, from which they can be mobilized into the bloodstream. At the same time, BMSCs may divide to yield undifferentiated progeny with identical BMSC characteristics, fulfilling the two criteria for a stem cell: self-renewal and the ability to give rise to differentiated progeny. Cell–cell and cell–matrix interactions are crucial to the proliferation and differentiation of HSCs in the bone marrow niche. Depending on the circumstances, HSCs can traffic from the marrow into the circulation in large numbers, a process termed *mobilization* (Cottler-Fox *et al.*, 2003). However, Kucia and Ratajczak (2005) propose that in addition to BMSCs, bone marrow harbors versatile subpopulations of tissue-committed stem cells (TCSC) and perhaps even more primitive pluripotent stem cells. Exogenous administration of granulocyte colony-stimulating factor (G-CSF) is the standard method of inducing stem and progenitor cell release into the circulation in a clinical setting (Cottler-Fox *et al.*, 2003). The chemokines interleukin 8 (IL-8) (Rothe *et al.*, 1998) and stromal-derived factor 1 (SDF-1)

(Hattori *et al.*, 2001) both participate in G-CSF-mediated stem cell mobilization. SDF-1 as well as VEGF and PlGF (vascular endothelial growth factor and placental growth factor, respectively) induce osteoclasts to secrete the metalloprotease MMP-9, whose action results in the shedding of the membrane-bound cytokine stem cell factor (SCF) from the bone marrow, releasing it into the circulation.

On activation, BMSCs proliferate and differentiate into progenitor cells that can be found in the peripheral blood (Ikuta *et al.*, 1992). These progenitor cells may then differentiate further as required. BMSCs have been reported to have the potential to differentiate into a variety of other tissues, including liver (Lagasse *et al.*, 2000), muscle (Ferrari *et al.*, 1998), and neuronal cells (Brazelton *et al.*, 2000; Eglitis and Mezey, 1997; Mezey *et al.*, 2000), thus demonstrating a role for stem cell plasticity in tissue maintenance and repair. Recent studies support the possibility that BMSCs may also have broad potential to differentiate into various ocular cell types (Chan-Ling *et al.*, 2006; Harris *et al.*, 2006). Lethally irradiated mice were reconstituted with HSCs from mice homozygous for green fluorescent protein (GFP<sup>+</sup>) and subjected to laser-induced Bruchs membrane rupture. GFP<sup>+</sup> retinal pigment epithelial cells, astrocytes, macrophages/microglia, pericytes, and vascular endothelial cells were observed in or adjacent to the wound site, confirming that HSCs have the capacity to differentiate into cells expressing different ocular phenotypes.

Postnatal neovascularization has previously been considered synonymous with proliferation and migration of preexisting endothelial cells resident within parent vessels, i.e., angiogenesis (Folkman, 1971). However, Asahara *et al.* (1997) identified cells derived from bone marrow capable of differentiating into neovasculature as CD34<sup>+</sup>-expressing cells. Thus, these cells presumably are key mediators of endothelial repair. We and others have demonstrated that HSCs provide functional hemangioblast activity during retinal and choroidal neovascularization (Grant, 2002, 2003; Espinosa-Heidmann *et al.*, 2005; Sengupta *et al.*, 2005; Takahashi *et al.*, 2004) and that HSCs give rise to a variety of lineages, including the CD34<sup>+</sup> EPCs. This mechanism of endothelial repair represents a significant source of cells for neoangiogenic vessels. Defects in EPC function appear to be responsible for the development and persistence of acellular capillaries in diabetic retinopathy, since lack of repair of acellular capillaries contributes to the development of retinal ischemia and represents an irreversible

step in the progression of this disease (Bresnick *et al.*, 1976; Fong *et al.*, 2004). EPCs isolated from patients with type 1 diabetes have a decreased rate of migration, and incubation with a nitric oxide (NO) donor alters the EPC cytoskeleton, normalizing their rate of migration (Segal *et al.*, 2006). EPC migration can be stimulated by activation of growth factor receptors (Herbrig *et al.*, 2004; T. Imanishi *et al.*, 2004; Kim *et al.*, 2005; Tepper *et al.*, 2005; Valgimigli *et al.*, 2004; Wu *et al.*, 2004), such as vascular endothelial growth factor 1 and 2 (VEGFR1 and VEGFR2), and cytokine receptors, such as CXCR4 (receptor for SDF-1) (De Falco *et al.*, 2004; Hiasa *et al.*, 2004; Valgimigli *et al.*, 2004; Yamaguchi *et al.*, 2003). Inhibiting SDF-1 has been shown to reduce the degree of stem cell involvement in induced neovascularization (Sengupta *et al.*, 2003). It also appears that autologous bone marrow-derived lineage negative HSCs containing endothelial progenitors stabilize and rescue retinal blood vessels in two mouse models of retinal degeneration (Otani *et al.*, 2004). Interestingly, this regeneration of retinal vessels was accompanied by neurotrophic rescue of the retina and preservation of cone vision.

## V. POTENTIAL FOR STEM CELLS IN OCULAR REPAIR AND TISSUE ENGINEERING

The realization of the existence of undifferentiated cells, which self-renew and show plasticity, in adult tissues offers great potential in the treatment of both ocular and nonocular diseases. It is now becoming evident that both intraocular and extraocular stem cells have the ability to play a critical role in the maintenance of ocular tissues. Furthermore, the plasticity of these cells means that they can be engineered to repair injured or diseased ocular tissues. Corneal limbal stem cells are now routinely used in the restoration of the injured ocular surface, and bone marrow stem cells hold great promise in the repair of retinal damage.

Stem cells are an ideal starting point for tissue engineering of ocular tissues and offer a means of therapeutic intervention in a variety of pathologies involving cell/tissue loss (e.g., age-related macular degeneration, retinitis pigmentosa, glaucoma, and diabetic retinopathy). The future will tell if these stem cells can be used to deliver normal genes to correct genetic abnormalities in specific ocular tissues.

### I. INTRODUCTION

Synthetic corneal replacements have been under speculative design for over 200 years. Recently developed advanced cell culture methods and the success of other engineered connective tissues (e.g., skin) have spurred numerous efforts since the early 1990s to produce engineered corneal tissue. Though there has been significant progress toward the development of synthetic corneal replacements and in the culturing of human corneal cells onto and within supporting natural substrates, in general the net results of these efforts has been somewhat disappointing. Currently two clinically viable synthetic cornea replacements and no clinically viable tissue-engineered corneas are approved for use in end-stage corneal disease. Given the relative success of tissue engineers in their approach to creating skin substitutes, the cornea would seem an attractive alternative next target. The lack of success is not surprising, for the cornea, unlike skin, comprises a highly organized stroma populated by three distinct cell types. Two particularly difficult problems must be resolved before suitable tissue-engineered corneal analogs can be generated: (1) replacement or replication of the ultrastructural arrangement of the stromal extracellular matrix and (2) generation of a reliable source of untransformed, proliferative corneal endothelial cells. In this chapter we review efforts to develop synthetic corneal analogs, examine the short history of corneal-tissue engineering, and present the latest methods that have shown promising results toward

the realization of functional tissue-engineered corneal replacements.

Corneal disease and injury are the second leading causes of vision loss, affecting over 10 million people worldwide (Whitcher *et al.*, 2001). The leading cause of corneal blindness in the Third World is trachoma (4.5 million people), followed by corneal injury (1.5 million people). The vast majority of these cases would benefit from a suitable corneal replacement. In developed countries such as the United States, conditions that indicate the use of donor corneal grafts include Fuch's dystrophy, keratoconus, pseudo and aphakic bullous keratopathy, corneal stromal dystrophies, corneal scarring, and herpes simplex virus. As of 2000, there were approximately 33,000 corneal transplants performed each year in the United States (Aiken-O'Neill and Mannis, 2002). Though the donor cornea *potential* far outstrips the need, there are real cultural, logistical, and technical difficulties associated with procurement of donor graft material. In addition, donor grafts are typically variable in quality and can fail due to immunological rejection or endothelial decompensation, resulting in a failure rate for initial grafts of approximately 18% (Thompson *et al.*, 2003). Finally, there is a rising threat to the number of viable donor corneas in the form of LASIK procedures, which automatically disqualify donor tissue for transplantation. It is thus of significant clinical interest to develop a suitable corneal replacement for donor graft material. There is also a need for corneal replacements that are insensitive to the loss of limbal stem

**FIG. 68.1.** Anatomy of the eye. The cornea is the transparent portion of the ocular tunic, which must protect the fragile intraocular contents, allow incident light to pass through to the retina, and provide a smooth optical interface for refraction. Figure from the National Eye Institute, National Institutes of Health.

cells. A constellation of diseases and injuries can destroy the stem niches or disrupt the delicate systems that maintain the ocular surface (severe chemical burns, Stevens-Johnson, Sjogren's, and ocular pemphigoid, etc). For these conditions, donor grafts are contraindicated and an alternative approach such as autologous stem cell transplantation (Schwab *et al.*, 2000) or an all synthetic optic (Yaghouti and Dohlman, 1999) is required. Nonetheless, design of any tissue replacement requires a detailed understanding of the function that was performed by the native tissue. It is instructive, then, to review the functional role that the cornea plays in the visual system. There are three principal design requirements for the natural cornea: (1) protection of the fragile intraocular contents, (2) transparency to visible light, and (3) formation of a nearly perfect optical interface to refract light onto the retina. Nature has evolved an extremely elegant structure capable of meeting these critical design criteria simultaneously.

### Gross Corneal Structure and Function

The cornea is the anteriormost, clear portion of the tough ocular tunic (see Fig. 68.1). Corneal tissue comprises one-sixth of the total ocular globe and is a highly structured, relatively acellular, transparent collagenous tissue that joins the more disorganized and opaque sclera at the limbus. Though not perfectly circular, the diameter of the human cornea is about 12 mm. The average radius of curvature of the central anterior surface is 7.8 mm, and it is roughly 520 microns thick at the center and 650 microns thick in the periphery.

**FIG. 68.2.** Variation in corneal tensile strength as a function of direction. Though the cornea is typically considered a simple nematic stack of lamellae comprising aligned collagen that alternate in orientation by 90°, recent investigations demonstrate an array of fibrils that run circumferentially around the periphery. Preferred fibril orientation and aligned fibril concentration are reflected in the tensile strength, or tensile modulus. The figure shows the tensile modulus found in test strips excised and loaded in the direction of the arrows.

### Protection

The tensile mechanical strength of the cornea is a critical design criterion, in that the ocular tunic must survive significant traumatic impacts without rupture. The overall biomechanical properties of the cornea are complex because the tissue is highly anisotropic (different properties in different directions), heterogeneous, and viscoelastic (reviewed in Ethier *et al.*, 2004). The preferred collagen fibril orientation is reflected in the measured tensile strength of test specimens. Figure 68.2 shows the tensile modulus of the cornea as a function of location and orientation of the excised test strip. The tensile moduli shown in the figure were obtained from test specimens that were aligned with the principal collagen fibril directions, as determined by x-ray analysis (Aghamohammadzadeh *et al.*, 2004) and SEM (Radner *et al.*, 1998; Radner and Mallinger, 2002).

The compressive properties of the cornea depend on its hydration and are primarily the result of the fixed negative charges bound to the stromal proteoglycans (Hedbys, 1961). At normal hydration there are approximately 40 mEq (Kostyuk *et al.*, 2002) of fixed negative charge, which imbues the cornea with a swelling pressure of approximately 60 mmHg (Hedbys *et al.*, 1963).

### Transmission of Light

At normal hydration, the cornea can transmit up 97% of the incident visible light (Cox *et al.*, 1970). This value depends on the relative water content and distribution in the stroma (Goldman *et al.*, 1968). It is important to note that the water content (and transparency) of the cornea is maintained by a complex transport system that requires a functioning endothelium (pump) and epithelium (barrier) to operate (reviewed in Ruberti and Klyce, 2002).

**FIG. 68.3.** The cornea (approximately 500 microns thick in humans) is a layered structure comprising the epithelium (E), Bowman's layer (Bw), stroma (St), Descemet's membrane (De), and the endothelium (En). Reproduced, with permission, from Klyce and Beuerman (1997).

### Refraction of Light

The combination of the nearly perfectly spherical corneal anterior surface and the index of refraction change at the air/tear film interface generates approximately 80% (42 diopters) of the total refractive power of the human visual system.

### Corneal Microscopic Structure and Function

Three distinct morphological layers are important to the function of the cornea: the epithelium, the stroma, and the endothelium. Figure 68.3 shows the orderly structure of the tissue and the relative dimensions of the three major layers.

#### Epithelium

The corneal epithelium is a 50- $\mu$ m-thick multicellular "tight" stratified squamous epithelium comprising three distinct functional cellular strata. The deepest cellular layer, the stratum germinatum, is the only layer capable of undergoing mitosis (Hanna and O'Brien, 1960). The middle layer comprises the daughter cells (wing cells) of the basal layer,

**FIG. 68.4.** Light micrograph of corneal epithelium and anterior stroma. Note stratified cell layer with basal cells (B), wing cells (W), and desquamating surface cells (D). Thin basal lamina (BL) resides at stromal epithelial interface. Bar is 20 microns. Reproduced, with permission, from Klyce and Beuerman (1997).

which are pushed anteriorly. The surface layer comprises the squamous cells that form the complete tight junctions that generate the primary *protective* barrier in the cornea. Like most squamous epithelia, the corneal epithelium is continually turned over (once every five to seven days; Hanna and O'Brien, 1960). This process depends on a stable supply of stem cells, which reside in niches at the junction between the cornea and the sclera (limbus) (Schermer *et al.*, 1986). A healthy epithelium has five to seven layers of cells and a basement membrane comprising laminin, type IV collagen, identifiable hemidesmosomes, and anchoring fibrils (Fig. 68.4).

Pathologies that chronically disrupt the ocular surface mucosa (ocular cicatricial pemphigoid, Stevens-Johnson syndrome, etc.) or disrupt tear production (Sjogren's) or injuries that destroy the limbal stem cell niches (severe chemical or alkali burns) are contraindications for donor grafts (and any future engineered cornea) because the ocular surface will not epithelialize or wet properly. Epithelial cells are derived from surface ectoderm during embryogenesis.

### Stroma

The stroma is putatively the secretory product of invading mesenchymal cells during development that populate and then expand the extracellular matrix in the potential corneal space between the lens and the nascent epithelium (Cintron *et al.*, 1983). In adults, the stroma is a relatively acellular (3–10% quiescent corneal keratocytes by volume) 500- $\mu\text{m}$  thick, extracellular matrix comprising hydrated type I/V heterotypic collagen fibrils (15% wet weight) of uniform diameter ( $\sim 32$  nm) in humans (Meek and Leonard, 1993); glycosaminoglycans (GAGs) keratan sulfate and dermatan sulfate (1% wet weight; Anseth, 1961); various proteoglycan (PG) core proteins (Axelsson and Heinegard, 1975); and other protein constituents, including fibronectin, laminin, and type VI collagen. The collagen fibrils are packed in 300–500 parallel arrays (lamellae) tangent to the corneal surface (Hamada *et al.*, 1972) and are principally responsible for the observed tensile mechanical properties of the cornea. The PGs and their associated GAGs contribute to the cornea's compressive and swelling material properties (Hedbys, 1961) and to the uniform spacing of the collagen fibrils.

### Endothelium

During development of the corneal endothelium, mesenchymal cells of neural crest origin migrate between the developing lens and the corneal epithelium. Endothelial cells are initially morphologically indistinct from stromal cells but begin to distinguish themselves by the formation of sinuous lateral borders, which interdigitate with adjacent cells to ultimately form the endothelial monolayer (Cintron *et al.*, 1988). In adults, the corneal endothelium is a transporting monolayer of approximately 400,000 hexagonal cells 20 microns in diameter and 4–6 microns in height (Fig. 68.5). This membrane is of critical importance to the maintenance of corneal transparency (reviewed in Ruberti and Klyce, 2002). It has long been known that the cornea is normally maintained in a state of relative deturgescence and that its tendency to imbibe fluid can cause swelling, opacity, and blindness. However, it was not until 1972 that Maurice discovered that the active mechanism that keeps the cornea dehydrated is a fluid pump located in the endothelium. This dehydrating mechanism is part of a sophisticated corneal transport system, which is described in detail in Ruberti and Klyce (2002). Nonetheless, the untransformed endothelial cells, which are critical to normal corneal function and which will be an important part of any tissue-engineered cornea, have, until recently (Engelmann *et al.*, 1999, 2004; Joyce and Zhu, 2004; McAlister *et al.*, 2005), been refractory to attempts at multiple expansions in culture.

### Stromal Ultrastructure

The corneal stroma comprises 90% of the total corneal thickness. It is thus not surprising that it plays a major role in providing the principal functions of the cornea (protec-

**FIG. 68.5.** Transverse (*top*:  $\times 3150$ ) and en face (*bottom*:  $\times 900$ ) electron micrographic views of the corneal endothelium. The en face view illustrates the hexagonal packing of the endothelial cells. Reproduced, with permission, from Beuerman and Pedroza (1996).

tion, transmission, and refraction). On close inspection, it is the exquisite *ultrastructural* organization of the stromal ECM that allows the cornea to meet these difficult design requirements. Figure 68.6 shows the organization of the corneal stromal collagen fibrils, which have a virtually monodisperse diameter distribution, uniform local interfibrillar spacing, and no interfibrillar covalent cross-links and are arranged in parallel arrays tangential to the corneal surface. This remarkable nanoscale arrangement of fibrils, which persists throughout the cornea, is *directly* responsible for corneal strength (Ethier *et al.*, 2004), clarity (Goldman *et al.*, 1968) and to some extent for its ability to refract light. The exquisite stromal organization is also the primary reason that attempts to produce a viable cornea via tissue engineering have, thus far, been unsuccessful. Any corneal analog comprising a collagenous extracellular matrix (ECM) must reproduce this arrangement or risk being too weak,

**FIG. 68.6.** Transmission electron micrograph of collagen fibril arrangement in cornea. Corneal collagen fibrils have a highly monodisperse diameter distribution and are arranged in oriented arrays within lamellae approximately 1–2 microns thick. (Section is normal to tangent plane.)

too opaque, or too irregular to form an appropriate refractive surface.

## II. SYNTHETIC CORNEAL REPLACEMENTS

Nondegradable synthetic corneal replacements, if ultimately successful, could obviate the need for donor corneas or tissue-engineered corneal constructs. As early as the 1700s, synthetic corneas were designed and implanted to give persons who had bilateral loss of eyesight finger-counting vision. Currently, synthetic corneas are indicated for persons affected by specific conditions, such as severe chemical burns, ocular pemphigoid, Stevens-Johnson syndrome, and recurrent graft rejections. In the late 1700s, one of the first documented efforts to develop a synthetic cornea was performed by Pellier de Quengsy (1789). In these trials he inserted a glass plate into an opaque eye. The plate was not stable and was rapidly extruded. Subsequently, efforts were made to stabilize the central optic with celluloid plates and egg membranes (Dimmer, 1891), plexiglass, and acrylate (Binder and Binder, 1956; Gyorffy, 1956) or supporting plates of solid or fenestrated poly(methylmethacrylate) (PMMA) (Castroviejo *et al.*, 1969). No effort was made either to achieve the correct refractive index or to optimize the corneal curvature. The constructs were not biocompatible, and as a consequence cellular ingrowth did not occur and the device was not anchored. These initial prostheses led to the development by Cardona (1964) of “through-and-through devices.”

Cardona was a pioneer in the development of kerato-prostheses and demonstrated that highly purified and polymerized materials could be maintained in the cornea. The materials first used by him were rigid, impermeable, and secured with sutures, and neither keratocyte ingrowth nor deposition of matrix proteins was reported. A number

of the devices protruded through the eyelid and used the surrounding tissue for stabilization. Devices of this style were used where lubrication of the cornea was minimal and often gave the person finger-counting vision. The more current Cardona devices include a PMMA optic surrounded by a perforated skirt of poly(tetrafluoroethylene) (PTFE) reinforced with a mesh composed of poly(ethylene) terephthalate (Dacron) and autologous tissue. The complexity of the device was matched only by the surgery, for the device is inserted through the eyelid, often requiring the removal of the lens, iris, and ocular muscles. Because there was no UV-absorbing tissue remaining, the optic was tinted to absorb UV irradiation. The final device often gave no more than 30° of visual field. These devices continued to be extruded because the material chosen for the periphery did not permit cellular ingrowth and the synthesis of matrix proteins. In contrast, the free edge permitted necrosis and allowed for epithelial downgrowth. Attempts to achieve interpenetration or anchoring of the material led to the development of the osteo-odontoprosthesis (OOKP) (Strampelli and Marchi, 1970). The premise of the Italian group was that a biological material would be more easily tolerated than a synthetic material. To manufacture their device, an acrylic optical core was embedded within the core of a tooth. The insertion of the device was complicated and was often accompanied by infiltration with vascularization, abscess formation, and extrusion. Blencke *et al.* (1978) modified the osteo-odonto prosthesis by replacing the tooth portion with a glass ceramic, which was again modified by Caiazza *et al.* (1990), who implanted a modified device using bone. These devices have been maintained for more than 12 years and continue to be used when surgery for penetrating keratoplasty is not suitable (Hille *et al.*, 2005).

By the 1980s, investigators proposed that biological acceptance and retention of through-and-through devices depended on the ability of stromal fibroblasts to migrate into the device and deposit a matrix. To allow tissue integration, White and Gona (1988) devised a device with a central optical cylinder of poly(methyl methacrylate) (PMMA) and a periphery of Proplast with pore sizes ranging from 80 to 400 microns. The device had a high extrusion rate and induced significant inflammatory responses. The next generation of porous skirt materials included the expanded poly(tetrafluoroethylene) (Impira) (White and Gona, 1988), carbon fibers that projected from the optic haptic as rays (Kain, 1990), and a melt-blown polybutylene:polypropylene web (Trinka-Randall *et al.*, 1991).

The development of the olyofinic webs (3M, St. Paul, MN) (Trinka-Randall *et al.*, 1990) was based on surgical mesh fabrics used in skin, muscle, and arterial wall. The optimal pore size determined in these tissues (Bobyn *et al.*, 1982; Cook *et al.*, 1989; Pourdeyimi, 1989) was used in the development of the pore size for the cornea. A fiber diameter that ranged from 2 to 12 microns with a void volume of 88% was found to be optimal in *in vitro* and *in vivo* studies

(Trinka-Randall *et al.*, 1990, 1991). Legeais *et al.* (1994, 1995) used a similar model and fabricated a device from skirt porous PTFE (IMPRA) using a pore size of 18–22 microns, which also permitted fibroplasia.

The biological response (deposition of matrix components) of the cornea to devices based on synthetic biomaterials is of paramount importance if they are to remain stable *in vivo*. Trinka-Randall *et al.* (1991) found that the deposition of types I and III collagen in synthetic discs did not increase significantly until day 21. More recently, Drubaix's observations (Drubaix *et al.*, 1996) supported the earlier data that there are changes in the synthesis of collagen and that they resemble that of an injured cornea (deposition of types I and III collagen). These early studies demonstrated that the tensile strength of the implant interface was not sufficient unless cellular ingrowth occurs (Chirila *et al.*, 1993). When the deposition and synthesis of glycosaminoglycans were evaluated, the migration of cells into the discs mimicked the scenario of wound repair (Funderburgh and Chandler, 1989; Cintron *et al.*, 1990; Brown *et al.*, 1995). Heparan sulfate, absent in control corneas, was detected, and Trinka-Randall and Nugent (1998) demonstrated that FGF-2 was present transiently at the margin between the synthetic discs and the stroma. Trinka-Randall *et al.* (1994) found that pretreatment (by plasma cleaning or by coating with biologically active molecules) enhanced collagen deposition fivefold, which was associated with increased fibroplasia and decreased edema.

The development of implantable synthetic optic materials has had a long and laborious history and seeks to produce a material that permits light transmission in the visible range and protects the retina from ultraviolet damage. The latter requires a modification to absorb light at wavelengths below 300 nm and is critical in devices where the lens has been removed. It should have tensile properties similar to that of a native cornea and allow for continuous reshaping of both anterior and posterior curvatures. Epithelialization is a point of controversy, and most investigators now support Dohlman's premise that it only makes care more difficult and can cause more difficulties, such as epithelial downgrowth (Dohlman *et al.*, 1974).

The most commonly used material, PMMA, has been made in ultraviolet-absorbing forms for intraocular lenses, can be shaped and retains clarity over time, exhibits low toxicity, and is well tolerated. However, it is both rigid and hydrophobic and has poor diffusivity.

Hydrogels were evaluated because they are elastic, can be manufactured to have high tensile strength and maintain transparency, and can be modified to support epithelial cell growth (Laroche *et al.*, 1989; Trinka-Randall *et al.*, 1994; Wu *et al.*, 1994; Latkany *et al.*, 1997). A poly(vinyl alcohol) hydrogel (refractive index of 1.42) was developed for use as an optic by Trinka-Randall *et al.* (1988). The hydrogel was prepared from a poly(vinyl trifluoroacetate) precursor and possessed a higher elasticity (436% vs. 15%) and tensile

strength (110 kg/cm<sup>2</sup> vs. 35 kg/cm<sup>2</sup>) than those of the intact cornea. It possessed a water content around 70%, which is similar to that of the cornea (79%). When ultraviolet absorbers (phenyl-benzotriazole and a benzophenone derivative) were copolymerized, transmission of ultraviolet light was not detected below 340 nm (Tsuk *et al.*, 1997). The surface of the poly(vinyl alcohol) hydrogel was modified to support epithelial cell growth and maintenance (Latkany *et al.*, 1997) by coating with ECM components or by plasma treatment. The epithelial cells became confluent and multilayered, displayed typical cytoarchitecture, showed a basal-apical polarity, and synthesized a typical repertoire of adhesion proteins *in vitro*. This was also detected *in vitro* when the surfaces were modified with the tripeptide RGD (Laroche *et al.*, 1989). However, when the discs were implanted *in vivo*, the apical surface of the cultured cells was altered, with the shearing force associated with blinking and the cells sloughed off the surface of the optic. Epithelialization has continued to be one of the most challenging tasks in the development of keratoprotheses.

Two synthetic corneas have been tested in humans. The first "biocolonizable" was implanted in 24 human patients, and five failures were reported in the first six months (Legeais *et al.*, 1995). In a second model, the optic was silicon coated with PVP and the surface remained hydrophilic. These devices were implanted in eyes with dystrophy's, pseudophakic edema, pemphigus, and burns. Unfortunately, signs of decolonization after 9–12 months were noted; however, they were used successfully as temporary devices, which could help patients with retinal and corneal pathologies (Dong *et al.*, 2006) awaiting a transplant.

Dohlman, who was instrumental in the development of keratoprotheses (Dohlman *et al.*, 1974), has reevaluated conditions having the best prognosis and what factors can be used as predictors of outcome (Dohlman, 1997). He has continued to use a multipiece plastic device that is not colonized; however, he has demonstrated that with meticulous follow-up the patients can have an excellent outcome. Eyes with graft failure had the best outcome, while those with chemical burn and Stevens-Johnson syndrome had the worst outcomes.

Chang (Chang *et al.*, 1995) used a silicone membrane altered by plasma-induced graft copolymerization-treated HEMA. It was sutured as a penetrating keratoplasty; however, the graft did not remain in the plane of the host cornea and extruded by three months. It is likely that stromal downgrowth occurred where the fibroblasts grew under and essentially formed a second cornea, gradually extruding the cornea.

A number of colonizable devices ranging in size (4.5–9 mm) and design were evaluated in rabbits using both penetrating keratoplasty and lamellar keratoplasty models (Trinka-Randall *et al.*, 1997). The time course of fibroplasia depended on the model and on the size of the porous skirt. The devices that were the most successful were those

**FIG. 68.7.** Dohlman-Doane keratoprosthesis. (A) Prosthesis shown with large-diameter donor tissue carrier and central optical cylinder comprising PMMA. (B) Prosthesis one day after implantation. Reproduced, with permission, from Aquavella *et al.* (2005).

**FIG. 68.8.** Alphacor™ keratoprosthesis. (A) PHEMA keratoprosthesis with central optical zone porous skirt. (B) Alphacor at 12 weeks immediately following second stage of procedure, during which the tissue anterior to the optical zone was removed. Reproduced, with permission, from Hicks *et al.* (2003).

where Descemet's membrane was left intact. They were placed as posterior as possible in the stromal lamellar bed, and the flanges were inserted into the stromal lamellae. Fibroplasia was detected between two and three weeks. Devices with larger skirts were not supported by the cornea in the long term, presumably because there was less diffusivity of nutrients. Smaller models (7 mm in diameter) were retained in rabbit corneas for a minimum of one year, the duration of the trial. Collagen types III and VI were detected after six weeks. Heparan sulfate, a GAG, absent in the unwounded stroma but present in injured stromas, was detected (Trinka-Randall and Nugent, 1998). In all of these models the anterior chamber remained intact and no sign of leakage was detected. Parel's group also used a rabbit lamellar keratoplasty model to assess their nonpenetrating device after eyes were injured and scarring and vascularization induced (Stoiber *et al.*, 2005). The most optimal model using synthetic materials is probably that of Chirila, where both the peripheral rim and the central optic are cross-linked polymers of HEMA (Chirila *et al.*, 1993). In this model the periphery was made from a hydrogel sponge. The sponge has a high water content (80% w/w), facilitating diffusivity through the material. Fibroplasia was detected when the devices were pretreated with type I collagen (Chirila *et al.*, 1993). The central optic was an HEMA-2 ethoxyethyl methacrylate acrylamide. The entire device, given the name AlphaCor™, has been implanted in human patients (Fig.

68.8). The change in visual acuity pre- and postop is remarkable, with preoperative acuity being finger counting and postoperative (20/200) (Hicks *et al.*, 2003). The studies have now focused on the role of the environment (i.e., medications, cigarette smoke) and on the long-term stability and integrity of the device. Calcium was detected as a white opacity, indicating that topical medications can modify the haptics (Morrison *et al.*, 2006). In addition, brown deposits were found to be a result of smoking (Hicks *et al.*, 2004). Both of these indicate that to maintain the stability of the devices, patient management is paramount.

### III. CORNEAL-TISSUE ENGINEERING

The cornea is a fairly simple, sparsely populated, avascular, multilaminar structure that, at first glance, would seem to be an attractive target for tissue engineers. The corneal cell population comprises three different cell types (epithelium, fibroblasts/keratocytes, and endothelium) that require successful culturing techniques if a cornea is to be constructed by tissue-engineering methods. The history of corneal tissue engineering begins with culturing epithelial cells onto collagen mats (Friend *et al.*, 1982; Geggel *et al.*, 1985) and has continued to the production of full-thickness, multilaminar, populated constructs grown on collagen/polymer scaffolds, complete with innervation (Li *et al.*, 2003). In spite of the success in populating collagen-based gels with epithelium, fibroblasts/keratocytes, and endothe-

limum, no corneal construct has been produced that is suitable for clinical use. There are two principal barriers to the production of a clinically viable cornea: (1) reproduction of a suitable corneal stromal analog and (2) the ability to populate the construct with viable human corneal endothelial cells. There has been significant progress on the latter problem (Joyce and Zhu, 2004), while the former has met with little documented success. Thus, at the moment it appears that the most critical barrier to successful tissue engineering of a cornea lies in the construction of a suitably strong, clear stromal matrix.

### A Note on Engineering and Tissue Engineering

Perhaps the difficulty of producing an appropriate tissue-engineered cornea might be discerned if the difference between the terms *tissue engineering* and *engineering* is examined. Engineering by its very nature employs a rational design approach that requires three things: (1) that we fully understand the design requirements of the structure to be produced (e.g., loads on the stanchions of a bridge); (2) that we have available at the time of construction a toolbox of fully characterized materials, devices, and systems that will be integrated to produce our engineered product (i.e., structural steel, concrete, etc.); and (3) that we have available methods that allow us to synthesize the components into the whole (i.e., nuts, bolts, hammers, etc.). In contrast, classical tissue-engineering methods are not rational, in that we often do not fully know the function of the tissue that is being engineered, we do not understand the properties of the materials (ECM components) and devices (cells) from which the final structure will be derived, and we have little idea about how the whole is assembled from the component parts. Why proceed without rationality, then? The answer, of course, is that we expect that the cells, which are typically seeded into/onto a degradable scaffold or “synthetic scar,” will appropriately remodel the scaffold such that intended tissue function is reproduced. This approach has been reasonably effective for tissues that do not depend *critically* on highly organized and often highly anisotropic tissue ultrastructure, such as skin. However, for the engineering of tissues whose principal function depends critically on the precise arrangement of extracellular matrix components (i.e., cornea, ligament, tendon etc.), the results have been less than satisfactory. We must surmise, then, that there is a limit to the ability of seeded fibroblasts to remodel scaffolds, which is similar to the remodeling of a scar and can be extremely slow (Cintron *et al.*, 1982). For the corneal stroma, whose function depends on the exquisite organization of the ECM, perhaps it is time to pursue a more circumspect course that seeks to take a rational design approach rather than relying solely on the cells “to put things right.” This can be accomplished either by attempting to construct the tissue ultrastructure *de novo* before cell seeding or by giving the seeded cells as many cues (mechanical, chemical, etc.) and as much support as possible to allow them to

construct an appropriate ECM. Nonetheless, it is clear that more information about fibroblastic cell-behavior modulators (i.e., strain, growth factors, etc.), ECM component properties, and ECM component assembly kinetics is required.

### Engineering Corneal Epithelium

The epithelium is responsible for the protection of the stroma and the maintenance of the tear film. Though it is not necessary to produce corneal constructs with adherent epithelia to replace failed corneas (donor corneas are debrided of their epithelium prior to implantation), it is important that they support the attachment, spreading, and, ultimately, growth to confluence of epithelial cells to form a robust anterior corneal barrier. In addition, there have been numerous recent attempts to reengineer the surface of stem cell-deficient corneas via autologous stem cell transplantation on carriers such as amniotic membrane (Gomes *et al.*, 2003). Finally, organotypic corneal culture systems for *in vitro* research do require an intact functional corneal epithelium. Stratified squamous epithelial cells possess minimal intrinsic differentiation differences (Sun and Green, 1977) and may alter their behavior/differentiation as a function of the culture system environment. It has also been demonstrated that epithelial cells, which are moderately difficult to culture, may be supported by soluble factors produced by cocultured fibroblastic cells (Green *et al.*, 1977) or by treatment with exogenous factors, including EGF (Savage and Cohen, 1973). These observations suggest that environmental stimuli and cell-derived soluble factors are responsible for the final differentiation of the cells, which implies that culturing systems may be “tuned” to elicit appropriate cell behavior. An ideal corneal epithelium would form a confluent multilayer (five to seven cell layers) stratified structure with complete tight junctions at the surface, desmosomes between the cells, and hemidesmosomes with anchoring fibrils projecting into an adherent BM.

### Corneal Epithelial Cell Culture on Substrates

Corneal epithelial cells were first isolated from rabbit corneas and reseeded directly onto tissue culture dishes to form a confluent monolayer in long-term investigations by Sundar-Raj *et al.* (1980). However, to engineer a suitable cornea for replacement purposes, it is important to grow the cells on an implantable substrate. Numerous studies have investigated the behavior of corneal epithelial cells that have been isolated and then reseeded onto various natural substrates (Savage and Cohen, 1973; Friend *et al.*, 1982; Geggel *et al.*, 1985; Trinkaus-Randall *et al.*, 1988, 1988). One of the first investigations of corneal epithelial cell behavior following isolation and seeding onto substrates (denuded rabbit corneal stroma with or without basement membrane (BM)) was conducted by Friend *et al.* (1982). The results demonstrated that isolated corneal epithelial cells will adhere, grow to confluence, and stratify (to three layers

*maximum*) on stromal carriers (with or without BM). In spite of the low number of cellular strata, the cells displayed microplacae, intracellular desmosomes, and normal-looking organelles. The major difference between cells seeded onto denuded stroma and those seeded onto residual basement membrane was that the cells seeded onto BM formed hemidesmosomes within one week. Cells seeded onto denuded stroma produced a BM within four days but did not generate hemidesmosomes for the period of the investigation. The next advance shifted the culturing of epithelium to reconstituted collagen instead of native corneal stromal tissue. This is a critical step in the development of an engineered cornea. In the study by Geggel *et al.* (1985), epithelial cells were lifted as an intact sheet from rabbit corneas and draped onto collagen gels, with the specific intent to *engineer* the ocular surface. The cells, which were grown on vitrogen gels in culture using SHEM (Jumblatt and Neufeld, 1983), maintained their confluence and apposition but did not stratify fully (only three layers) and lacked basement membrane components. Notably, the vitrogen disc was well tolerated for six weeks *in vivo*, with little induced inflammation or degradation of the onlay.

In 1988, Trinkaus-Randall *et al.* (1988) demonstrated that corneal basal epithelial cells (Trinkaus-Randall and Gipson, 1985) respond differently depending on the nature of the substrate on which they were plated: fibronectin, laminin type IV, or type I collagen. Their results suggest that laminin and type I collagen significantly enhance cell proliferation and support the growth and attachment (via sites of adhesion) of a normal-looking epithelium *in vitro*.

*Airlifting* is one of the more significant cell culture developments and was adapted from methods used to culture skin keratinocytes (Prunieras *et al.*, 1983) by Minami *et al.* (1993). Minami cultured bovine epithelial cells to subconfluence on a reconstituted type I collagen gel and then aspirated the medium until the cells on the gel surface were just exposed to (fully humidified) air. By 21 days, the epithelium formed a confluent multilaminar (six layers of cells) that stratified into three morphologically distinct cellular layers (basal, wing, and superficial). Distinct desmosomes were observed between cells, as was a fragmentary basal lamina on the collagen gel side of the epithelium. It is important to note that Minami performed this investigation as part of a full corneal reconstruction, with both keratocytes and endothelial cells present in the constructs. The paper noted that the *presence of the other cell lines enhanced epithelial proliferation and differentiation* as compared to controls on bare collagen gels. In a more comprehensive investigation, Zieske *et al.* (1994) cultured untransformed rabbit epithelium on untransformed rabbit keratocyte-populated collagen gels at a wet, dry, or moist interface, with or without mouse corneal endothelium (immortalized cell line). Zieske noted a profound influence of the endothelial cells (which were plated directly onto the reconstituted collagenous stroma) on the assembly of epithelial basement

**FIG. 68.9.** Light micrograph of stratified corneal epithelium grown using airlift technique and in organotypic, coculture with endothelium and keratocytes. Reproduced, with permission, from Zieske *et al.* (1994). Bar = 50 microns.

membrane and epithelial cell differentiation. In the presence of the endothelium, (1) the epithelium forms an identifiable basement membrane, (2) the epithelial basal cells become more columnar, (3)  $\alpha$ -enolase is restricted to the cells in the basal layer, (4) collagen IV and laminin localize to a continuous layer at the stromal–epithelium interface, and (5)  $\alpha$ 6 integrin becomes localized to the stromal side of the basal cells. Figure 68.9 shows the morphology of the epithelium grown at the moist air interface and in the presence of the endothelial cells.

### Engineering Human Corneal Epithelium

Culture of human corneal epithelial cells onto collagen-based substrates for the purposes of corneal tissue engineering has been performed with reasonable success (Ohji *et al.*, 1994; Germain *et al.*, 1999; Griffith *et al.*, 1999; Li *et al.*, 2003). Ohji *et al.* (1994) demonstrated that primary cultures of human epithelial cells produce basement membrane components (laminin, collagen type IV, collagen type VII, and perlecan) when cultured on stromal blocks or on collagen gels (with or without fibroblasts present). This study demonstrated the feasibility of culturing human epithelial cells on collagen gels. (See Protocol 68.1.)

In her seminal paper in which the three types of human corneal cells were used to generate an artificial cornea, May Griffith (Griffith *et al.*, 1999) obtained the “best results” through the use of immortalized epithelial cell lines that had been screened for biochemical, electrophysiological, and morphological similarities to low-passage human primary cells. Unfortunately, the parameters that critically define the patency of healthy corneal epithelium (basement membrane components, desmosomes, hemidesmosomes, tight junctions, etc.) were not described in the paper. It should be noted that Griffith’s group has focused on the task of

**Protocol 68.1** Cell culture protocol of Ohji *et al.* (1994).

**Cell isolation: Epithelial cells.** Human corneal epithelial cell sheets were derived from  $2 \times 2$ -mm limbal explants of donor corneas. Explants were placed epithelial side up in 35-mm culture dishes using modified SHEM and were incubated at 37°C and 5% CO<sub>2</sub> 95% air for 12–15 days to gain confluency of epithelial cells (explants were removed at 10 days). Sheets of cells were lifted using dispase II. **Keratocytes.** Human keratocytes were derived from the central cornea of donor eyes. Explants were cultured in the modified SHEM for eight days and then moved, prior to keratocyte outgrowth, to 35-mm dishes and bathed in modified Eagle's medium containing 15% FBS and 40-μg/mL gentamicin sulfate. Confluent keratocyte cultures were lifted using trypsin (0.05%) and EDTA (0.02%). Media was changed once per week, and passages four to seven were used.

**Medium:** The medium used to support the cells in culture was a modified version of the SHEM (supplemented hormonal epithelial medium) of Jumblatt and Neufeld (1983), which contained DMEM-HEPES, Hams F-12, 15% FCS, 0.5% DMSO, 20 μg/mL gentamicin, 10 μg/mL EGF, 5 μg/mL insulin, 5 mM L-glutamine, and 0.1 mg/mL cholera toxin.

**Substrate preparation:** Debrided stromal collagen blocks were used for one study, and collagen gels derived from acid-soluble type I collagen were used for another. Vitrogen-100® was gelled (by neutralization and warming) in the presence of FBS with or without isolated human keratocytes. The total gel volume was 1.5 mL, and the keratocyte seeding count was  $5 \times 10^5$  cells.

**Seeding/culturing protocol:** Epithelial cell sheets were placed onto stromal blocks or onto the collagen gels and covered with 1 mL of medium. One day 22 mL of medium was added to the dish, and the medium was changed every two to three days. The cell/gel constructs were harvested at one, two, three, and four weeks.

**Protocol 68.2** Cell culture protocol of Germain *et al.* (1999).

**Cell isolation: Epithelial cells.** Human corneal epithelial sheets were teased from excised limbal annuli following exposure to dispase II neutral in 10 mM HEPES calcium chloride (1 mM) for 18 h at 4°C. The sheets were cut into small pieces and centrifuged for 10 min at  $200 \times g$  at 20°C. The cells were seeded onto 25-cm<sup>2</sup> culture flasks with irradiated 3T3 fibroblasts in DME-HAM. **Keratocytes.** Human keratocytes were obtained from a mixed culture of fibroblasts and epithelial cells after culturing in fibroblast medium. Passages two to nine were used.

**Medium:** Epithelial medium (DME-HAM): Combination of Dulbecco–Vogt modified Eagle's medium (DME) with Ham's F12 in 3 : 1 ratio, supplemented with 24.3 μg/mL adenine, 5 μg/mL insulin,  $2 \times 10^{-9}$  M 3,3',5'-triiodo-L-thyronine, 5 μg/mL human transferrin, 0.4 μg/mL hydrocortisone,  $10^{-10}$  M cholera toxin, 10% fetal clone II newborn calf serum, 10 ng/mL human EGF, 100 IU/mL penicillin G, and 25 μg/mL gentamycin sulfate. Keratocyte medium: DME with 10% FCS antibiotics.

**Substrate preparation:** 9.5 mL of 2.8 mg/mL acetic acid extracted bovine dermal collagen (neutralized) and 1.0 mL DME containing  $2.5\text{--}3.5 \times 10^5$  human corneal fibroblasts were mixed rapidly at 4°C with 5.6 mL DME and 3.7 mL FCS. 2.0 mL of the solution was poured into a 35-mm petri dish containing an anchorage (filter paper). The collagen was gelled at 37°C and covered with the keratocyte medium.

**Seeding/culturing protocol:**  $3.8 \times 10^6$  epithelial cells in 0.4 mL of DME-HAM were added to the keratocyte/collagen substrate (after four days of culture). The cells were allowed to attach for 2 h before adding 2 mL of additional DME-HAM. The medium was changed daily, and biopsies were taken after three days.

constructing stromal analogs that promote neurite ingrowth (Li *et al.*, 2003). Their motivation is derived from the well-known fact that loss of sensory innervation affects the corneal epithelium and, in particular, slows epithelial healing rates (Araki *et al.*, 1994). It is possible that improving neurite population rates may improve outcomes; however, current donor corneal graft neurons are necessarily severed from their roots, and epithelial failures are not a prominent cause of graft loss.

Though immortalized cells are useful tools for studying behavior *in vitro* (culture methods for immortalized cells are not reviewed), untransformed cells hold the greatest promise for production of an engineered corneal replacement. The location of epithelial harvesting of cells is important because there are spatial differences in the proliferative

capacity of human corneal epithelial cells (Lindberg *et al.*, 1993). Limbally derived explants show the greatest ability to undergo multiple passages in culture. Two investigations have used primary human corneal epithelial cells for the purpose of corneal-tissue engineering (Germain *et al.*, 1999; Orwin and Hubel, 2000). In the first one (see Protocol 68.2), Germain *et al.* (1999) cultured primary human limbal epithelial cells onto collagen gels populated with primary human keratocytes. The cocultured epithelium stratified within three days with cuboidal basal cells and elongated suprabasal cells. Epithelial basal cells expressed  $\beta 1$ ,  $\alpha 3$ ,  $\alpha 5$ , and  $\alpha 6$  integrin subunits within 10 days (three submerged and seven at air–liquid interface). Laminin and type VII collagen was localized to the basal cell cytoplasm and to the junction of the epithelium and stroma within 10 days.

Orwin and Hubel cultured untransformed human epithelial cells, keratocytes, and endothelial cells alone or in combination onto specially constructed collagen sponges

**Protocol 68.3** Cell culture protocol of Orwin and Hubel (2000).

**Cell isolation: Epithelial cells.** Human epithelial cells were isolated from excised human corneas by gentle scraping following incubation overnight at 4°C in dispase (1.5 mg/mL) in Hanks balanced salt solution. The cells were seeded into a tissue culture flask at  $2 \times 10^4$  cells/cm<sup>2</sup> in the epithelial medium. **Keratocytes.** Human keratocytes were obtained following collagenase digestion (37°C overnight) of debrided corneas. The keratocytes were washed and resuspended in the keratocyte medium. **Endothelial cells.** Human endothelial cells were trypsinized from the cornea, swabbed off, centrifuged, and seeded into tissue culture flasks at 8500 cells/cm<sup>2</sup> in endothelial medium.

**Media: Epithelial medium:** Keratinocyte growth medium (modified MCDB 153, Clonetics, Walkersville, MD) supplemented with 5 µg/mL insulin, 0.18 µg/mL hydrocortisone, 0.4% bovine pituitary extract, and 1 ng/mL EGF. **Keratocyte medium:** DMEM-F12/HAM with 10% FCS. **Endothelium medium:** MEM supplemented with 10% FBS, 0.292 mg/mL L-glutamine, 0.014 µl/mL 2-mercaptoethanol, 13.13 mg/mL chondroitin sulfate, 1 mM sodium pyruvate, and 0.1 mM nonessential amino acids.

**Substrate preparation:** Collagen sponges were prepared with acid-treated bovine hyde. Washed bovine corium was frozen, lyophilized, and ground to produce particles 83–125 microns in size. Collagen dispersions 0.5% wt/vol were blended with HCL to pH 3.0 at 4°C for 1 min. The dispersion was the lyophilized at –30°C and dehydrothermally cross-linked in a vacuum at 110°C/2.5

torr for five days. The sponges were gamma irradiated (17,500 rads). Prior to seeding, the sponges were cut into 14-mm-dia × 1–2-mm-thick disks and hydrated with 150 µL of media.

**Seeding/culturing protocol: Single cells:** Epithelial, keratocyte, or endothelial cells were seeded onto 14-mm-diameter × 1–2-mm thick sponges at 118,000 cells/cm<sup>2</sup> and allowed to sit at 37°C for one to two hours. Following attachment, 1 mL of media was applied to the culture dish. Every other day, 4 mL of fresh media were added to the dish for a duration of 21 days. **Cocultures:** (1) Epithelium/endothelium on same sponge. Endothelium was seeded on the center of the smooth side of the sponge and allowed to attach at 37°C in 5% CO<sub>2</sub> for 1–2 h. The dish was then supplemented with media and incubated overnight. The sponges were inverted and epithelium was seeded on the porous side in 50 µL of media. Following 1–2 h for attachment, the dish was supplemented every other day with equal parts of endothelial and epithelial media for 14 days. (2) Epithelium on sponge, endothelium cultured on other side of transwell membrane. The same protocol as before, but the epithelial cells were cultured on the bottom of a flask and the epithelial cells were cultured on the sponge, on top of a transwell insert. (3) Keratocytes in sponge, epithelium on sponge. Keratocytes were seeded onto the porous side of the sponge and cultured for three days. On day 4, epithelial cells were seeded onto the sponge surface and allowed to attach. Sponges were supplemented every other day with equal parts epithelial and keratocyte media for 15 days.

(Orwin and Hubel, 2000) (see Protocol 68.3). They found that coculture of epithelial cells and endothelial cells (cultured on the sponge or separated by a transwell insert) produced the highest degree of epithelial cell layering (two to four layers of cells). However, airlift techniques were not used in this study, and the specific markers of basement membrane formation, tight junction formation, or desmosome formation were not investigated.

### Summary of Epithelium in Culture

In summary, there is a long history of culturing primary corneal epithelial cells onto substrates with the intent of producing a morphologically appropriate epithelial membrane. The net results indicate that a reasonably mimetic (albeit thin) corneal epithelium can be produced *in vitro* if the substrate has appropriate components (type I collagen or laminin), if there are other cells (preferably endothelium) cocultured along with epithelial cells, if the medium is suitable, and if the culture is airlifted. Under these conditions, the epithelial cells will stratify to produce a multilaminar

architecture and will generate basement membrane components spontaneously. However, the history of culturing *human* epithelial cells is shorter, and there have been fewer assessments on the nature of the epithelium that has been produced. Specifically, there have been no studies that have shown formation of a reasonably continuous basement membrane with anchoring fibrils and associated hemidesmosomes. There have also been no long-term studies of human epithelial cultures. Nonetheless, progress to date has been good, and it is likely that further attempts to epithelialize tissue constructs with human cells await the production of a more appropriate stromal analog.

### Engineering the Corneal Stroma

The corneal stroma is an exquisitely organized collagen–proteoglycan composite matrix populated sparsely by quiescent keratocytes. The stromal architecture provides high mechanical strength (Ethier *et al.*, 2004) and optimal curvature for refraction and allows light to pass virtually unimpeded (Goldman *et al.*, 1968). The keratocyte popula-

tion also plays an important role in maintaining corneal clarity by index matching through expression of water-soluble corneal crystallin proteins (Jester *et al.*, 1999). Any tissue-engineered corneal construct must reproduce the function of the corneal stroma, or, as has been the case thus far, it will fail to achieve utility in the clinic. As with epithelial cell culturing, there has been some success in populating natural substrates with corneal fibroblasts/keratocytes. On the other hand, very little progress has been made toward producing a suitably strong, clear corneal stromal matrix into which corneal fibroblasts may be seeded.

### Keratocyte Cultures

In the human cornea *in vivo*, the stroma contains a sparse, quiescent (for an alternative view, see Muller *et al.*, 1995) network of index-matched, dendritic cells termed *keratocytes*. Human corneal keratocytes (HCKs) are distributed throughout the tissue and are thought to maintain the stroma through the continual production of stromal proteoglycans (Hassell *et al.*, 1992) and possibly proteins (Muller *et al.*, 1995). Upon corneal wounding, keratocytes can dedifferentiate into or are replaced by fibroblasts and myofibroblasts (Garana *et al.*, 1992), which participate in the normal wound-healing process. Corneal myofibroblasts are thought to play an important role in wound contraction (Jester *et al.*, 1987; Garana *et al.*, 1992), while corneal fibroblasts are synthetically active and can be induced to produce matrix components *in vitro* (Newsome *et al.*, 1974; Stoesser *et al.*, 1978). It was noted in the early 1970s that human corneal keratocytes are more proliferative under certain culture conditions (see Protocol 68.4) than either corneal epithelium or endothelium (Newsome *et al.*, 1974). Newsome *et al.* found that keratocytes (they actually had a fibroblastic morphology) migrated from explants after four days and then overran the epithelial cell layers that had emerged from the explant earlier. This was one of the first indications that HCKs could be grown successfully in large numbers in culture. However, it is important to understand the mutability of the keratocyte phenotype if stromal tissue is to be engineered. Normal stromas contain quiescent keratocytes, while wounded stromas contain fibroblastic and myofibroblastic phenotypes as well. In culture, the conversion of keratocytes from their quiescent phenotype to a fibroblastic phenotype is thought to be induced by the presence of serum in the medium (Beales *et al.*, 1999), while the differentiation to a myofibroblastic phenotype can be induced by adding TGF- $\beta$  (Jester *et al.*, 1996). There is also evidence of the partial reversibility of fibroblasts to keratocyte morphology following the removal of the serum in the medium (Berryhill *et al.*, 2002). Reversion of fibroblasts to keratocyte phenotype, which possess corneal crystallins (aldehyde dehydrogenase) in large quantities, will ultimately be important for restoration of stromal transparency (Jester *et al.*, 1999). Most stromal analogs in tissue-engineered corneas include serum

#### Protocol 68.4 Cell culture protocol of Newsome *et al.* (1974).

**Cell isolation: Epithelial cells, endothelial cells, and keratocytes.** Human corneal cells were allowed to migrate from the explants of cadavers between the ages of 18 and 68. Eyes were enucleated within eight hours of death and stored at 4°C in 0.85% NaCl for no more than 32 hours. Explants of 1 × 2 × 5-mm of central corneal epithelium, Bowman's, and superficial stroma were used for the epithelial and keratocyte culture, while strips of Descemet's were used for the endothelial culture. The explants were rinsed twice in saline G (Puck's N-15 minus the amino acids) and placed into culture dishes with a sterile coverslip on top of them. Primary outgrowths of the cells between 10 and 20 mm in diameter were propagated by washing in Ca<sup>++</sup>- and Mg<sup>++</sup>-free PBS followed by incubation for 20 min at 37.5°C in 1.0 mL of Coon's enzyme (six units collagenase per mL, 0.1% trypsin, and 2.0% chick serum) with 4 mM EDTA for epithelium and endothelium and without EDTA for keratocytes. The suspended cells were pipetted onto new dishes containing growth medium.

**Media: Growth medium:** Modified Ham's F12 with 5% FCS and 3  $\mu$ g/mL penicillin.

**Seeding/culturing protocol:** Cells were pipetted onto 60-mm plastic culture dishes or into 30-mL plastic tissue-culture flask. Media was changed every three days.

in the keratocyte medium (Germain *et al.*, 1999; Griffith *et al.*, 1999; Orwin and Hubel, 2000), which should induce the transformation to a fibroblastic phenotype and can induce contraction of collagen gel-based stromal substrates (Borderie *et al.*, 1999) as well.

### Keratocytes in Resorbable Scaffolds

To date, with the exception of some data reported in conference abstracts (Guo *et al.*, 2002; Germain *et al.*, 2004), stromal analogs for tissue-engineered corneas are created by seeding keratocytes/fibroblasts into collagen-based resorbable scaffoldings (Borderie *et al.*, 1999; Germain *et al.*, 1999; Griffith *et al.*, 1999; Orwin and Hubel, 2000). Unfortunately, there are very few data on the phenotype, synthetic, and catabolic behavior of corneal fibroblasts in such systems. However, it is known that corneal fibroblasts in three-dimensional collagen gels will organize into orthogonal arrays (Doane and Birk, 1991) and secrete type I, type V, and type VI collagen (Borderie *et al.*, 1999). Without long-term studies of the remodeling of such stromal analogs, it is not possible to comment on the potential of the classical resorbable scaffolding approach to corneal-tissue engineering. Nonetheless, the process of keratocyte-driven remodeling of a degradable scaffolding is likely to resemble stromal scar resolution, which, even under ideal conditions

*in vivo*, can take years (Cintron *et al.*, 1982). If this fact is coupled with the difficult requirement that an implanted resorbing scaffold retain its clarity and mechanical strength during the remodeling process, then the prospect of developing a suitable cell-seeded resorbable system appears to be remote.

#### Keratocytes in Scaffold-Free Systems

Development of the mammalian corneal stroma takes place under specialized conditions in a very thin layer between the epithelium and the nascent lens (Cintron *et al.*, 1983). It is possible that the rapid development of highly organized matrix can take place only under conditions that include a high density of synthetic cells (Cintron *et al.*, 1983) in a confined space (Martin *et al.*, 2000). Under appropriate conditions, human corneal fibroblasts cultured on plates at high density form multiple layers of cells that alternate in the orientation of their long axes by 90° in adjacent layers (Newsome *et al.*, 1974). Newsome also found that high-density cultures of human corneal fibroblasts deposit large quantities of extracellular fibrils (10–15 nm in diameter). Stimulation of collagen production by the addition of ascorbic acid to corneal fibroblast culture media has been demonstrated by Stoesser *et al.* (1978) and in general fibroblast cultures by Grinnell *et al.* (1989). Two laboratories have attempted to produce corneal stromal analogs in scaffold-free systems by stimulation of matrix production using ascorbic acid derivatives (Guo *et al.*, 2002; Germain *et al.*, 2004). In the investigation by Guo *et al.*, untransformed human corneal fibroblasts produced stroma-like arrays of alternating collagen fibrils embedded in a stratified cell–matrix construct (see Fig. 68.10). The most striking aspect of the cell-assembled constructs is their resemblance to the matrix produced during development *in vivo*. In particular, the alternating arrays of collagen, the stratification of the active keratocytes, and the high cellular density are all found in developing stroma as well (Cintron *et al.*, 1983). The ability of untransformed human corneal fibroblasts to produce organized arrays of collagen when stimulated is a very tantalizing development in the pursuit of an engineered cornea. Further details on this approach, detailed methods, and results await publication in the open literature.

#### Generation of Stromal Analogs

Corneal stromal–tissue engineering is derived primarily from cell culture techniques that began with the seeding of corneal epithelial cells on denuded stromal carriers in the early 1980s (Friend *et al.*, 1982). This was quickly followed by the seeding of cells onto reconstituted type I collagen gels, which formed an ersatz stroma, with the specific intent of reengineering the corneal surface (Geggel *et al.*, 1985). Simple, reconstituted type I collagen derived from bovine skin or from rat tail tendon was used by many investigators interested in constructing stromal analogs (Geggel *et al.*,

**FIG. 68.10.** Transmission electron micrographs of developing cell-assembled stroma. **(A)** Developing rabbit stroma in 21-day-old fetus. Image from Cintron *et al.* (1983). **(B)** Five-week scaffold-free stromal construct produced by untransformed human corneal fibroblasts in culture. Note synthetically active stromal cells and orthogonal arrangement of fibrils in lamellae.

1985; Minami *et al.*, 1993; Ohji *et al.*, 1994; Zieske *et al.*, 1994; Germain *et al.*, 1999). Acid-soluble collagen monomers such as Vitrogen-100® (which claims 80% type I collagen in monomeric form) can be purchased in quantity and form gels reliably by neutralization with NaOH followed by warming to 37°C. The resulting gels are weak, possess low density, are disorganized, and comprise long, native-looking type I collagen fibrils. Reconstituted type I collagen gels are highly biocompatible and can be gently gelled around a population of corneal fibroblasts (Germain *et al.*, 1999) but are not known to be particularly stable *in vivo* or *in vitro* without some form of cross-linking (Charulatha and Rajaram, 1997). To improve the stability of their reconstituted type I collagen stromal analog, Griffith *et al.* (1999) exposed the gel to 0.03–0.04% glutaraldehyde to cross-link it and then treated the gel with glycine to scavenge the unbound glutaraldehyde. Because of the known importance of glycosaminoglycans as

structural molecules (Hedbys, 1961) in the cornea, chondroitin sulfate was also added to the collagen-based stromal analogs of Griffith (Griffith *et al.*, 1999). The net result of the cross-linking and addition of GAGs to the simple type I collagen gel, followed by human fibroblast seeding, produced a clear, populated corneal stroma (Fig. 68.11). Unfortunately, the details of the resulting stromal architecture were not thoroughly investigated, nor were the mechanical properties, so our ability to evaluate the success of this formulation is limited.

Reconstituted type I collagen gels typically comprise very low-density, randomly arranged arrays of collagen fibrils and possess difficult-to-control porosity and poor mechanical properties. In an effort to manipulate the mechanical properties and pore size of collagen constructs, Orwin and Hubel (2000) constructed stromal analogs that began with collagen fibrils (bovine corium) formed into sponges by grinding, lyophilization, and dehydrothermal (DHT) cross-linking. The sponges supported colonization by human primary epithelium, endothelium, and keratocytes alone or in combination (epithelium/endothelium or epithelium/keratocytes) *in vitro*. The details of the stromal matrix/keratocyte interaction was investigated to a limited extent and demonstrated that the keratocytes colonized and proliferated on the sponges (Fig. 68.12). The keratocytes also appeared to align with fibrils and to synthesize matrix components (collagen and proteoglycans).

In a separate study, Orwin *et al.* (2003) added exogenous chondroitin sulfate and/or hyaluronic acid to their collagen sponges and assessed the resulting mechanical and optical properties. Ultimately, the collagen sponges were better mechanically and optically than collagen gels but were substantially inferior to native corneas (equilibrium compressive modulus was three orders of magnitude smaller than native cornea; transparency was, at best, half of native

**FIG. 68.12.** H&E-stained stromal analog of Orwin and Hubel. (A) By day 10 of culture, the cells have migrated through the stromal sponge. (B) By day 22 of culture, cells have elongated along the collagen fibers. Reproduced, with permission, from Orwin and Hubel (2000).

**FIG. 68.13.** Photographic comparison of the TERP5-collagen composite of Li *et al.* (2003) (B) and a reconstituted type I collagen gel (C). Reproduced, with permission, from Li *et al.* (2003).

corneal transparency). Clearly, the difficulty of constructing a suitably strong and clear corneal stromal analog has hampered attempts to produce a full-thickness engineered cornea. In response to this difficulty, Griffith's research group abandoned natural scaffolds and investigated hybrid collagen-synthetic copolymers as potential stromal analogs (Li *et al.*, 2003). The copolymer [poly(*N*-isopropylacrylamide-coacrylic acid-coacryloxysuccinimide), PNiPAAm-coAAc-coASI, or TERP] was used because it spontaneously cross-links proteins and anchors peptides through primary amines. The TERP and a second formulation, TERP5, in which some of the acryloxysuccinimide groups were reacted with YIGSR (to facilitate neurite extension and epithelial cell growth), were mixed with bovine collagen and molded to produce a controlled-thickness cornea. The resulting stromal analogs were clear (Fig. 68.13) and epithelialized well *in vitro*, with significantly more layers of cells (five) on the collagen-TERP5 constructs. The TERP5 and TERP matrices both promoted neurite ingrowth and were strong enough to be sutured (unlike the collagen-only gels). Implantation of the collagen-TERP5 stromal construct into micropigs (by LKP, leaving the posterior cornea and endothelium intact) demonstrated quiet integration of the copolymer matrix, rapid epithelialization (including the deposition of type VII collagen at the epithelial-matrix interface) by the host, and an enhanced rate of reinnervation over allografts. However, though the stromal constructs were suturable, care had to be taken to prevent cracking and damage during implantation. The authors state outright that their stromal construct is weak (but did not quantify the strength directly) as compared to native corneal stroma. This is probably due to the random arrangement and low density (3.4% wt/vol) of the collagen-polymer matrix. Unfortunately, the ability of neurites to populate the collagen-TERP5 constructs is quite possibly dependent on the density of the matrix, and any improvement in strength (by increasing the density) could be offset by a reduction in the rate of neurite migration.

### Summary of Stromal-Tissue Engineering

As has been demonstrated, the ability to culture human primary stromal keratocytes has advanced rapidly. The control of their differentiation state, contractile behavior, and ability to promote the secretion of matrix components by stimulation with adjuncts like TGF- $\beta$  and derivatives of ascorbic acid are all promising. However, the true difficulty associated with producing a corneal stromal analog is the exerting of control over the assembly and/or remodeling of the ECM. Understandably, the focus of most investigators has been primarily the behavior of the cellular constituents. The extracellular matrix, in spite of its dominant role in corneal function, has been, until recently, largely disregarded. Reconstituted type I collagen gels or fibrils have performed a useful but temporary role to aid in the study of primary human corneal cell behavior in culture. Their use is derived from their known biocompatibility and success in the tissue engineering of skin (Auger *et al.*, 1998). However, ultrastructurally, a cell-populated, reconstituted type I collagen gel (with or without cross-links or glycosaminoglycans) bears little resemblance to a real corneal stroma (except for the fact that both contain type I collagen and keratocytes). Since the principal functions of the cornea (mechanical integrity and clarity) are *directly* tied to stromal nanoscale structure, it is not surprising that the tissue-engineered corneas generated thus far are typically either not acceptably clear, not acceptably strong, or neither clear nor strong enough for use in the clinic. The problem with using self-assembled random arrays of collagen as a starting point for corneal-tissue engineering can be appreciated in Fig. 68.14, which shows SEMs of a self-assembled collagen gel and the cell-synthesized collagen in human cornea.

The ability of fibroblasts to remodel a randomly arranged collagen gel (as in Fig. 68.14B), either *in vitro* or *in vivo*, appears to be limited. Support for this point of view was provided by Cintron in his seminal work on the remodeling of rabbit trephination wounds (Cintron *et al.*, 1982). Cintron

**FIG. 68.14.** Scanning electron micrographs of a reconstituted type I collagen gel (A) and the cell-assembled collagen in a native human cornea (B). In the native cornea, arrays of highly organized fibrils split and pass above and below lamellae with different orientations. Current tissue-engineering methods expect seeded cells to resorb and replace randomly arranged collagen with highly organized collagenous matrix. The ability to exert control over the entropic randomization of self-assembled collagen in order to produce a more organized stromal analog may reduce the burden on seeded cells. The image in (B) is reproduced, with permission, from Radner *et al.* (1998).

found that fibrin-filled, full-thickness wounds in young rabbits were not successfully remodeled after two years! The process of primary fibroblast-driven remodeling of a scaffold or synthetic scar (regardless of its composition) is likely to occur on a similar time scale. For tissues that are highly organized and anisotropic, such as the corneal stroma or tendons, it is thus unlikely that remodeling (either *in vitro* or *in vivo*) can reproduce the native structure in a reasonable period of time. The exquisite organization of highly oriented connective tissue such as cornea was produced in a completely different environment during morphogenesis (Cintron *et al.*, 1983). If a natural corneal stromal analog is to be engineered, we must either provide a similar environment to actively synthetic fibroblasts or focus on ways to control the organization of the collagen *de novo* on the benchtop. Indeed, recent work has demonstrated that untransformed human corneal fibroblasts can be induced to produce a stroma-like matrix (Guo *et al.*, 2002). As discussed, the ability to generate suitable natural stromal scaffold *de novo* (on the benchtop) is in its infancy, but methods such as spin-coating (Ruberti *et al.*, 2003) of collagen already offer some control over collagen assembly (see Fig. 68.15).

Tight control over collagen fibrillogenesis could make the production of suitably strong, clear, natural stromal possible in the near future. In addition, aligned collagen films or simply substrates with nano-scale aligned features may be used to guide the migration of fibroblasts to control the deposition of collagen arrays in scaffold-free systems similar to that of Guo *et al.* (2002).

### Engineering the Corneal Endothelium

Because of the large swelling pressure in the normal corneal stroma (Hedbys *et al.*, 1963) and the lack of interfibrillar cross-linking, corneal tissue has a tendency to imbibe fluid. In 1972, David Maurice determined that the mechanism responsible for countering the swelling pressure and

**FIG. 68.15.** Optical differential interference contrast image of collagen aligned on glass substrate. Collagen fibrils were self-assembled in a flowing confined film to control their orientation. Bar is 10 microns.

keeping the cornea in a state of relative deturgescence (and thus transparent) is an active transporter located in the corneal endothelium. A functioning confluent endothelial layer is not only a critical component of the corneal transport system; it has also been shown to influence positively the structure and behavior of corneal epithelium when cocultured (Zieske *et al.*, 1994; Orwin and Hubel, 2000). Thus, even if the stromal analog comprises a material that does not require “pumping down” to become transparent, the unknown signaling molecules derived from a functioning endothelium may still be required to generate a functional tissue-engineered cornea. However, the difficult task of supplying enough vital, differentiated, and functional untransformed human corneal endothelial cells (HCECs) to

populate the construct requires solution. Fortunately, good progress has been made recently in this area.

### Endothelial Proliferative Capacity

Unlike other mammals, such as rabbit and pig, human corneal endothelial cells do not replicate *in vivo*; instead, they change their shape and spread to cover exposed Descemet's membrane following the loss of neighboring cells (Yee *et al.*, 1985). As a matter of course, corneal endothelial cell density declines in normal eyes from a postnatal value of 3000 cells/mm<sup>2</sup> at a rate of 0.5% per year (Bourne and Kaufman, 1976), yet adequate pump function is maintained throughout life. However, acceleration of the rate of normal endothelial cell loss through dystrophy, disease, or trauma (cataract surgery) can lead to declining visual acuity if the cell count drops below 500 cells/mm<sup>2</sup>. Because the endothelial decompensation secondary to cell loss is irreversible *in vivo* (which is a leading indicator for corneal transplantation), there has been significant effort expended to understand why the cells do not replicate and to develop methods to induce their proliferation (reviewed in Engelmann *et al.*, 2004; Joyce and Zhu, 2004). Naturally, these studies have led to attempts to culture primary human corneal endothelial cells *in vitro* and have provided an excellent set of tools that may be extended to induce the colonization of engineered stromal constructs (Joyce and Zhu, 2004). Investigators have demonstrated that, *in vivo*, human corneal endothelial cells are actively maintained in a nonreplicative state but have found that they *do* retain their proliferative capacity and can be successfully cultured onto human stromas (Bohnke *et al.*, 1999; Engelmann *et al.*, 1999; Chen *et al.*, 2001). Transfection with SV40 large-T antigen has been used to generate higher numbers of HCECs (Feldman *et al.*, 1993), which are functional when cultured on denuded human stromas (Aboalchamat *et al.*, 1999). However, the use of immortalized cell lines to produce tissue-engineered corneas for the clinic is controversial and will not be discussed further. Instead, methods used to enhance the proliferative capacity of untransformed HCECs show the most promise for corneal regeneration (Joyce and Zhu, 2004; Engelmann *et al.*, 2004) and are discussed next.

### Expansion and Culture of Corneal Endothelial Cells

Though cell culture techniques have been developed for animal endothelium (Perlman and Baum, 1974; Perlman *et al.*, 1974; Gospodarowicz *et al.*, 1977; Giguere *et al.*, 1982; Savion *et al.*, 1982), they are largely ineffective when applied to adult human corneal endothelium (Newsome *et al.*, 1974). HCECs that are contact inhibited and arrested in the G1 phase of the cell cycle (Joyce *et al.*, 1996a, 1996b) are perniciously nonproliferative, and unique culture methods have evolved specifically for them (Engelmann *et al.*, 1999; Chen *et al.*, 2001). Adult HCECs have been shown to proliferate to some extent *in vitro* when stimulated by appropriate mitogens (such as FBS, FGF, EGF) (Nayak and Binder, 1984)

and/or by growth on appropriate matrix components (such as fibronectin, laminin, bovine endothelial elaborated ECM) (Samples *et al.*, 1991; Blake *et al.*, 1997). Additionally, disruption of the cell-cell junctions with EDTA can elicit a proliferative response (Senoo *et al.*, 2000), as can mechanical wounding (Senoo and Joyce, 2000). Laboratories working on the expansion of HCECs in culture have reported that cells from younger eyes (<30) can be cultured more readily than cells from older eyes (Baum *et al.*, 1979; Nayak and Binder, 1984; Samples *et al.*, 1991). Attempts to induce the proliferation of HCECs in culture have produced several multiparametric studies that have tested the effectiveness of various media components (Nayak and Binder, 1984; Engelmann *et al.*, 1988; Engelmann and Friedl, 1989, 1995; Yue *et al.*, 1989). However, the results of these investigations have been somewhat equivocal and have not demonstrated the ability to culture adult HCECs for multiple passages or at high densities (reviewed in Engelmann *et al.*, 2004; Joyce and Zhu, 2004). Only recently has the culture, expansion, and transplantation of HCECs from both young and old donor eyes been reasonably successful (Engelmann *et al.*, 1999; Chen *et al.*, 2001). Engelmann *et al.* (1999) attempted to seed adult donor HCECs onto the denuded stromas from different donors in culture. Their corneal endothelial isolation procedure is complex (see Protocol 68.5) and employs the use of selection medium which substitutes L-valine for D-valine to inhibit the growth of contaminating fibroblastic cells, which can overrun the HCEC culture. The potential for fibroblast contamination arises from the use of concentrated collagenase (type IV) to release the endothelial cells, because it may also release fibroblasts from the underlying stroma. Engelmann found optimal seeding densities of 2–5 × 10<sup>5</sup> cells per 0.3–0.5 mL of fluid and that gentle centrifugation immediately following seeding aided in the attachment of the seeded cells to the recipient stroma. In spite of the careful protocol, a certain percentage of the cultured cells (not given) exhibited fibroblastic morphology and did not transfer well to the recipient stromas. Of the cultures that did exhibit polygonal morphology, the highest cell density was achieved at 11–12 days and was 1850 cells/mm<sup>2</sup> (mean 865, range 200–1850 cells/mm<sup>2</sup>). Final density counts were independent of donor age, length of time of recipient cornea culturing (before seeding), the number of passages of seeded cells, or the presence of FGF (though FGF did improve the cell morphology). Recipient corneas with seeded endothelium exhibiting a polygonal monolayer deswelled at rates comparable to controls, indicating that pump function was established (however, the sample number was small). In spite of the ability to culture endothelial cells for multiple passages and for long periods, the mean endothelial density on the recipient stromas was still low as compared to normals.

Recently the laboratory of Dr. Joyce has been successful in inducing the proliferation of HCECs in culture (Chen *et al.*, 2001; Joyce and Zhu, 2004; Zhu and Joyce, 2004; Konomi

**Protocol 68.5** Endothelial cell culture protocol of Engelmann *et al.* (1999).

**Cell isolation:** Corneas were removed from donor eyes (age 30–70) and stored in MEM medium supplemented with 10% FCS and 1% chondroitin sulfate at 37°C for up to three months. To extract the HCECs, Engelmann first disrupted the cell–cell connections with trypsin EDTA and then disrupted the ECM under the cells with collagenase (type IV). Specifically, the corneas were placed on plastic dishes, endothelium side up, and a few drops of enzyme solution (EDTA/Trypsin, 0.02%/0.8% in HEPES buffered saline) was added to the endothelium and left for 90 minutes at 37°C. Collagenase (type IV) in high concentration (0.5%) in a 1 : 1 mixture of Ham's F12 and Iscove's DME (IF) was then applied to the endothelium for 90 minutes at 37°C to undercut the cells. This was sometimes followed by collagenase treatment at low concentrations (0.04% or 0.025%) for 17 hours. The HCECs were dislodged with 20 mL of IF injected through a small needle. Cell suspensions were concentrated at  $900 \times g$  for 10 min and resuspended in 0.5 mL of the selection medium. They were then seeded in one well of a 24-well plat and maintained at 37°C and in 5% CO<sub>2</sub> to generate confluent primary cultures.

**Media:** *Selection medium:* The L-valine-free “selection medium” comprised IF plus 7.5% predialyzed, CM-preadsorbed, NCS and FCS (see paper for details of dialysis method for NCS and FCS), 0.08% chondroitin sulfate, 0.4 µg/mL FGF, and 50 mg/mL gentamycin. *F99:* 1 : 1

mixture of M199 and Ham's F12), supplemented with 10% FCS.

**Preparation of recipient cornea:** Human donor corneas were cultured in MEM supplemented with 2% FCS, 6% dextran, and penicillin [100 E/mL/streptomycin (100 µg/mL)] for 24 hours prior to denuding. Endothelial cells were denuded mechanically with a cotton swab, chemically by incubation with 10 mL of 0.04 M/L ammonium hydroxide for 5–10 min or physically by freezing to –80°C in 5 mL of MEM supplemented with 20% FCS. Typan blue was used to confirm full removal of the recipient HCECs. Freeze–thaw devitalization worked best and was the method of choice for the investigation.

**Seeding protocol:** Cultured monolayers of cells were harvested by exposure to 0.05% trypsin/0.02% EDTA. Cell counts from  $5 \times 10^4$  to  $5 \times 10^5$  were suspended in varying volumes of F99 (0.2–0.5 mL). Cell suspensions were “dropped” via pipette onto the denuded Descemet's membrane of a supported recipient cornea. The seeded supported corneas were placed in 50-mL Falcon tubes and centrifuged at  $33 \times g$  for 5 min. The corneal discs were then transferred to 2-cm<sup>2</sup> dishes for organ culture.

**Corneal organ culture protocol:** Recipient corneas were cultured in F99 for 7–20 days with decreasing concentrations of FCS (days 1–2, 10%; days 3–5, 5%; days 5–20, 2%).

*et al.*, 2005). In 2001, her laboratory successfully cultured HCECs from donors 50–80 years old onto denuded Descemet's membrane of recipient corneas (see Protocol 68.6). Transplanted endothelial cell densities averaged 1900 cells/mm<sup>2</sup> at 14 days, which approaches cell densities achieved using transformed cells (Aboalchamat *et al.*, 1999) and is double the value obtained by Engelmann *et al.* (1999). Earlier passages (primary through P3) averaged greater than 1500 cells/mm<sup>2</sup>, but later passages decreased the yield significantly. None of the cultures exhibited fibroblast morphology, but some cells did appear enlarged and exhibited characteristics of senescent cells. The key differences in the culturing technique over previous methods were associated with the isolation technique for the HCECs, the lower concentration of FGF, and the inclusion of EGF, NGF, and bovine pituitary extract. The cultures exhibited enhanced longevity if the EGF, NGF, and pituitary extract were removed from the medium and the FBS concentration was reduced to 4%. Comparison of the effect of growth-promoting agents on young and old donors suggests that older cells in any medium have slower doubling times and generally produce a lower cell density. To obtain successful HCEC cultures, the Joyce laboratory provides some selection criteria and methodological tips: (1) Donors with traumatic injury or

acute illness produced more successful cultures than donors with chronic illnesses. (2) Donors should have high endothelial cell density ( $>1500$  cells/mm<sup>2</sup>). (3) Corneas should be preserved within 12 hours of death in optisol-GF and immediately cultured on arrival in the laboratory from the supplier. (4) Maximal numbers of healthy cells for culture are more readily obtained following overnight incubation of Descemet's membrane strips in FBS (8%). (5) Attachment of cells overnight to FNC-coated culture dishes indicates healthy cells. (6) Cells that are moderately elongated when attached represent healthy cells.

### Summary for Engineering the Corneal Endothelium

Recently, extremely encouraging results have been realized for the culturing of untransformed human corneal endothelial cells, which have generally resisted expansion in culture (Engelmann *et al.*, 2004; Joyce and Zhu, 2004). For the first time, the possibility of transplanting untransformed HCECs into patients or seeding HCECs in high density on artificial corneal constructs appears plausible. For tissue-engineered corneas, the ability to culture endothelial cells onto the stromal construct will likely enhance the chemical milieu and promote better epithelial morphological development (Zieske *et al.*, 1994). If the stromal construct exhibits

**Protocol 68.6** Endothelial cell culture protocol of Chen *et al.* (2000).

**Cell isolation:** Donor corneas (age 50–80 yr) were preserved in Optisol-GS and shipped to the laboratory on wet ice. Corneas were washed with M199 with gentamicin (50 µg/mL). Descemet's membrane with intact endothelium was excised in small strips and incubated in OptiMEM-I with 8% FBS overnight to stabilize the cells. The strips were centrifuged, washed in Hank's balanced salt solution, and incubated in 0.02% EDTA at 37°C for 1 h to loosen cell–cell junctions. Mechanical isolation of the cells was accomplished by forcing tissue and medium multiple times through the narrow opening in a flame-polished pipette. The cells and Descemet's strips were pelleted and resuspended in culture medium.

**Media:** *Culture medium:* Optimen-I, 8% FBS, FGF 40 ng/mL, EGF 5 ng/mL, NGF 20 ng/mL, human lipids 0.005%, RPMI-1640 multiple vitamin solution, ascorbic acid 20 µg/mL, calcium chloride 200 mg/L, 0.08% chondroitin sulfate, gentamicin 50 µg/mL, and antibiotic/antimycotic solution diluted 1 : 100. Pituitary extract was added and human lipids and RPMI-1640 multiple vitamin solution were removed in later studies (Joyce and Zhu, 2004).

**Preparation of recipient cornea:** Descemet's membrane of the recipient cornea was denuded by treatment with 0.02 N of ammonium hydroxide and 0.5% sodium deoxycholate, followed by washing five times with 5 mmol/L EDTA. The cornea was washed one time with culture medium and placed, Descemet's up, in a six-well tissue culture plate using a sterile concave plastic support.

**Seeding protocol:** Cultured monolayers of cells in primary or passage 1 were harvested by trypsinization and centrifuged and resuspended to a concentration of  $25 \times 10^5$  to  $5.0 \times 10^5$ . Cell suspensions were gently applied in small aliquots onto the denuded Descemet's membrane of a supported recipient cornea. Each aliquot was incubated at 37°C for 1 h, the medium was aspirated, and the seeding step was repeated until all of the cells were applied. Corneas were incubated overnight at 37°C.

**Corneal organ culture protocol:** Recipient corneas were cultured in culture medium for one week and then in culture medium without growth factors (but with serum for an additional week).

a tendency to swell and becomes opaque (similar to a native corneal stroma), then a functional endothelium will be necessary to reduce edema and promote transparency. The ability to culture untransformed HCECs is a major advance toward the goal of producing a tissue-engineered cornea.

#### IV. CURRENT STATE OF CORNEAL-TISSUE ENGINEERING AND FUTURE DIRECTIONS

As a multilaminar structure, the cornea affords opportunities for reconstruction of each of the layers separately or in combination. Thus, diseases of each layer may be addressed without disruption of the entire structure. There have already been attempts to resurface the cornea using autologous limbal stem cell transplants alone or on amniotic membrane (Tsai *et al.*, 2000; Gomes *et al.*, 2003), and methods can now be envisioned that may allow the replacement of the corneal endothelium (Chen *et al.*, 2001; Zhu and

Joyce, 2004). Stromal replacement via synthetic optics is currently possible as well, but these implants remove the need for the limiting cell layers as a matter of course (Yaghouti and Dohlman, 1999; Chirila, 2001). A truly tissue-engineered corneal construct, which includes all three human cell types (untransformed) incorporated into and onto a natural stroma, has been an elusive target. Only Orwin and Hubel (2000) have cultured all three untransformed human cell types onto a collagen matrix ("sponge"). The result was too weak and too opaque for clinical consideration, and the colonization of the constructs did not produce convincing cellular strata. In general, the ability to culture the three corneal cell types *ex vivo* has improved to the point where the focus must now shift to the generation of a suitable stromal scaffold that will be functional at the time of implantation. Because of the long time scales associated with scar resolution *in vivo*, it is probably unreasonable to expect rapid resorption and remodeling of a degradable scaffolding that really is analogous to an artificial scar.

### I. INTRODUCTION

This chapter provides an overview of visual system properties in health and disease, with an emphasis on the stages in visual-signal processing that are most commonly affected by disease and dysfunction. It then provides an overview of current approaches to vision restoration and of approaches that promise to migrate from the lab to the clinic in the coming years. In a third section the potential roles for engineered cells and tissues in this restoration process are discussed. The chapter closes with an estimate of the developments that can be expected to occur in the next 5–10 years.

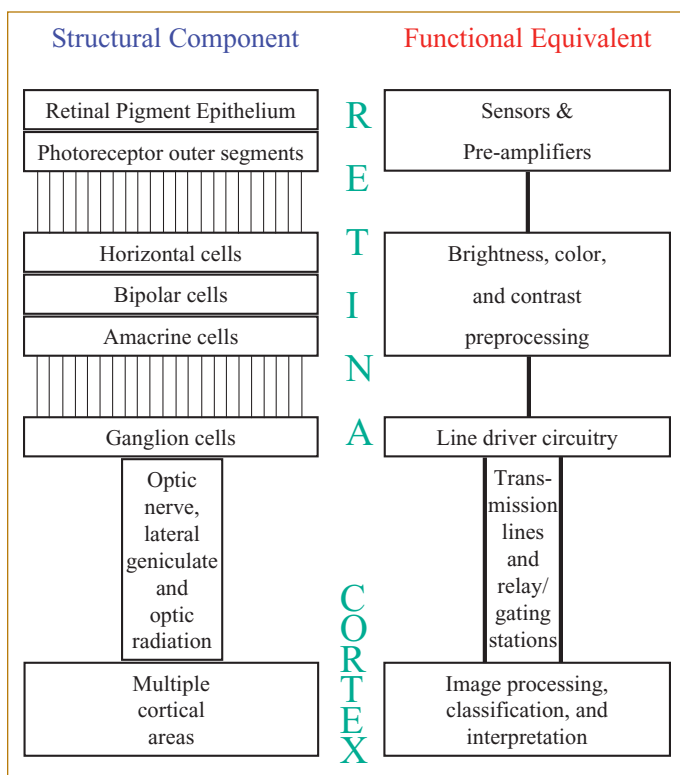

Twenty years ago, the best hope vision researchers had for the enhancement of impaired vision was to build a better magnifier by integrating optics and electronic image processing. Since then, restoration of vision to functionally blind individuals has become not just an engineering target, but a realistic goal for which engineering milestones are being set and reached. The role of tissue engineering in this field may as yet be modest, but it has great promise, as will become clear in the following pages.

In this chapter's overview of approaches to the restoration and enhancement of impaired vision in human patients, inspired by tissue-engineering principles and related technologies, we argue that the nature of eye disease and the

fragility and complexity of ocular tissues such as the neural retina do not (yet) lend themselves to application of the techniques emerging in the repair of other tissues. Thus, while some of the approaches presented here can function independent of tissue engineering as presented elsewhere in this volume, they at least complement those engineering approaches and lend themselves to future integration. This is particularly true in the areas of cell transplantation and neural prosthesis development, presented in the later part of this chapter, but to a lesser extent also for the optical and optoelectronic aids presented.

### II. VISUAL SYSTEM, ARCHITECTURE, AND (DYS)FUNCTION

Human vision is mediated by one of the most highly developed sensory systems found anywhere in nature. Its capacity to combine high spatial resolution near the center of fixation with a wide peripheral field of view, accurate depth perception, color discrimination, and light–dark adaptation over 12 orders of magnitude is unparalleled. Every stage in the system is organized to accomplish this: The photoreceptor layer in the retina provides the high signal amplification of the rods required for night vision and the dense packing of three cone types required for detailed

**FIG. 69.1.** Schematic representation of the visual system. The outer retina (RPE and photoreceptor layers) forms the sensor array, followed by several inner retinal preprocessing stages, the ganglion cell transmission stages, and further central processing stages in subcortical and cortical brain centers.

central and color vision. The intricate local preprocessing performed by subsequent retinal-cell layers augments these functions by performing brightness and color comparisons and helps to reduce the information stream acquired by over 100 million photoreceptors, to allow transport across a mere 1 million fibers in the optic nerve to the visual centers in the brain, where further parsing and interpretation of the image takes place.

From a functional point of view, the visual system can be understood as depicted in Fig. 69.1: with sensors, pre-amplifiers, preprocessors, transmission lines, and several central processor stages. The two most crucial stages in this process — the conversion from light into chemical and electrical signals, and the signal transmission from the eyes toward the brain — are also the most vulnerable ones. Light conversion and signal amplification in the photoreceptors require a highly complex interplay between the molecules inside these cells and ion channels and other permeable structures in the cell membrane. These components participate in interlocking cycles of conversion and regeneration and are assisted by surrounding cells — in particular the retinal pigmented epithelium (RPE) cells, which provide nutrients to, and digest cell membrane discarded from, the

photoreceptors. Any step in this intricate process can easily be disrupted by nutritional deficits, overexposure to short-wavelength light (presumably causing oxidative changes), attacks by pathogens, and especially genetic miscoding of one or more participating molecules. Since the mid-1980s, the list of mapped (>160) and identified (>120) genes has grown at an ever-increasing rate. For each identified gene there are multiple known mutations, often leading to distinct disease phenotypes; for an up-to-date list of the known mutations leading to loss of outer retinal function, see the Retnet website (Daiger *et al.*, 1996–2006). Not only do such mutations directly cause impaired signal transduction, but the additional energy demand, presence of abnormal molecules, and excess shedded cell membrane may exceed the RPE cells' support capacity, which inexorably leads to degeneration of both photoreceptors and RPE cells. The most common group of disorders caused by genetic miscoding of molecules involved in the phototransduction cycle is jointly known as *retinitis pigmentosa* (RP), while another group is caused by a breakdown of RPE function in the central retina due to either a genetic defect (Stargardt macular dystrophy) or a combination of genetic predisposition and environmental factors (age-related macular degeneration, AMD). Jointly, all these disorders are known as *retinal degenerations* (Fig. 69.2A and B).

Retinal neurons communicate in a variety of ways, with ion-gating channels fulfilling a role in reaching and maintaining an operating level (also known as the adaptation state) and neurotransmitters and gap junctions fulfilling the principal messenger roles in carrying information in chemical and electrical form, respectively. The loss of outer retinal function, and therefore of neurochemical and electrical signal transmission to the inner retina, will affect secondary retinal cells (horizontal, bipolar, amacrine, and ganglion cells) but not necessarily threaten their survival. Until a few years ago, morphometric studies of donor retinal tissue such as that shown in Fig. 69.2B suggested survival of bipolar and ganglion cells at rates of 80% and 30% in the macula (Santos *et al.*, 1997) and 40% and 20% at eccentricities up to 25° (Humayun *et al.*, 1999a), respectively, in retinas practically devoid of photoreceptors. In recent years, a series of highly detailed and elegant microanatomical studies using a technique called *computational molecular phenotyping* (CMP; Jones and Marc, 2005) has demonstrated that the connectivity patterns of these inner retinal-cell populations are fundamentally altered by the degeneration process (Fig. 69.3): Survival of these cells is predicated on their continued activity, and this they accomplish through the formation of new axonal and dendritic branches and through self-organization into clusters called *microneuromas*. These new and functionally random connections allow spontaneous oscillations to occur, in the absence of meaningful input signals from the erstwhile photoreceptors; RP patients may experience such spontaneous activities as photopsias, or “light shows” (Heckenlively, 1988).

**FIG. 69.2.** Representative samples of ocular morphology in healthy and diseased conditions. **(A)** Cross section through the retina near its center (fovea), showing healthy photoreceptor outer segments (POS), multiple layers of photoreceptor cell nuclei in the outer nuclear layer (ONL; labeled black), bipolar cell nuclei in the inner nuclear layer (INL), and ganglion cell bodies in the ganglion cell layer (GCL). **(B)** Retina of a patient with a long history of retinal degeneration and bare light perception in the last years of life, showing lack of photoreceptor outer segments and cell bodies in comparison with micrograph A. **(C)** Scanning electron microscope cross section of the optic nerve head, showing healthy appearance of the support structure, the lamina cribrosa. **(D)** Optic nerve head from a patient with long history of glaucoma, showing compression of the lamina cribrosa and embedded nerve fibers (RGC axons). **FIG. 69.3.** Simplified schematic of possible alterations during retinal remodeling. The first panel shows a representative “native” mammalian retina with its basic complement of rods (R) and cones (C) driving bipolar (B) and horizontal (H) cells. In turn, bipolar cells drive amacrine (A) and ganglion cells (G) of the proximal retina to form the major cone-OFF (sublayer *a*), cone-ON (sublayer *b*), and rod-ON (sublayer *r*) zones of the inner plexiform layer (IPL). Remodeling occurs in phases, as indicated under each panel. In phase 1, rod and cone stress leads to truncation of outer segments (1) and, in some instances, extension of rod (2) and cone (3) axons deep into the inner nuclear (inl), inner plexiform, and even ganglion cell (gcl) layers. Both rod and cone bipolar cells truncate their dendrites (4, 5), and some rod bipolar cells may transiently switch to surviving cones (not shown). Horizontal cells also send axons into the inner plexiform layer (6). Phase 2 is a complex period of cell death, ablation of the outer nuclear layer (onl), and resolution of the distal margin of the neural retina into a largely confluent glial seal (7) formed by the distal processes of Müller cells. Surviving neurons may continue to alter their phenotypes by changing receptor expression patterns (8), and some cone cells may even escape cell death (C). Neural remodeling becomes even more extensive during phase 3, with formation of complex axon fascicles (9) and new synaptic complexes termed *microneuromas* (10). As remodeling continues throughout life, some neurons begin to migrate along glial columns (11), others die (12), and the inner plexiform layer becomes transformed through new synapse formation (13) and laminar deformation (14). © 2005 Robert E. Marc. Used by permission.

At the retinal output signal transmission stage, where retinal ganglion cells (RGCs) convert the neurotransmitter signals into electrical spike trains that travel along RGC axons toward the thalamic relay nuclei and other brain areas, the system is vulnerable to mechanical insults rather than to genetic dysfunction: injury to the optic nerve (trauma), increased pressure inside the eye [crushing the fragile axon fibers at the optic nerve head (glaucoma)], and inflammation (optic neuritis) or impaired blood supply (ischemic neuropathy) of the optic nerve itself. Each of these can impair or interrupt the signal-carrying capacity of optic nerve fibers (Fig. 69.2C/D).

In addition to damage occurring at these distinct stages, more generalized damage to the retina can occur. Common mechanisms for this are the leakage of capillaries in diabetic retinopathy and the interruption of the blood supply to the inner retina (retinal vascular occlusive disease), especially in individuals with a predisposition toward the development of blood clots. Each of these can lead to widespread cell death in the inner nuclear and ganglion cell layers throughout the affected area; vascular occlusive disease provokes angiogenesis; the new retinal vessels tend to leak and damage the retina's fragile structure. Diabetic retinopathy is a major cause of preventable blindness in the developed world and increasingly in developing countries as well.

### III. CURRENT AND NEAR-TERM APPROACHES TO VISION RESTORATION

As in all biomedical engineering, approaches to restore function can be based on reversal of the disease process and regeneration of autologous tissue (on tissue grafts) or on hybrid techniques involving tissue as well as synthetic materials and devices. To support the cells affected by disease or injury, neuroprotective substances, growth factors, and genetic modifications of cell function may be used, postponing or preventing further loss of function. In addition, as long as useful function remains, one can strengthen the stimulus and internal response signal, counteracting visual impairment as much as possible.

If little or no sensor function remains, one can seek to restore it in limited form through newly grown or transplanted photoreceptors and/or RPE cells, through a prosthetic device that will electrically stimulate the remaining secondary retinal cells, or through man-made tissues that mimic photoreceptor function. At the RGC level, substitution for lost signal transmission may be sought through protection of any remaining cells and administration of factors promoting axon regeneration. This may require the use of synthetic tissues and factors enabling reconnection of axons with central structures — or through *in situ* growth of new cells, promoted to differentiate into RGCs and to send new axons through the optic nerve.

In preliminary form, some of these approaches exist in the laboratory and even begin to reach the clinic, while

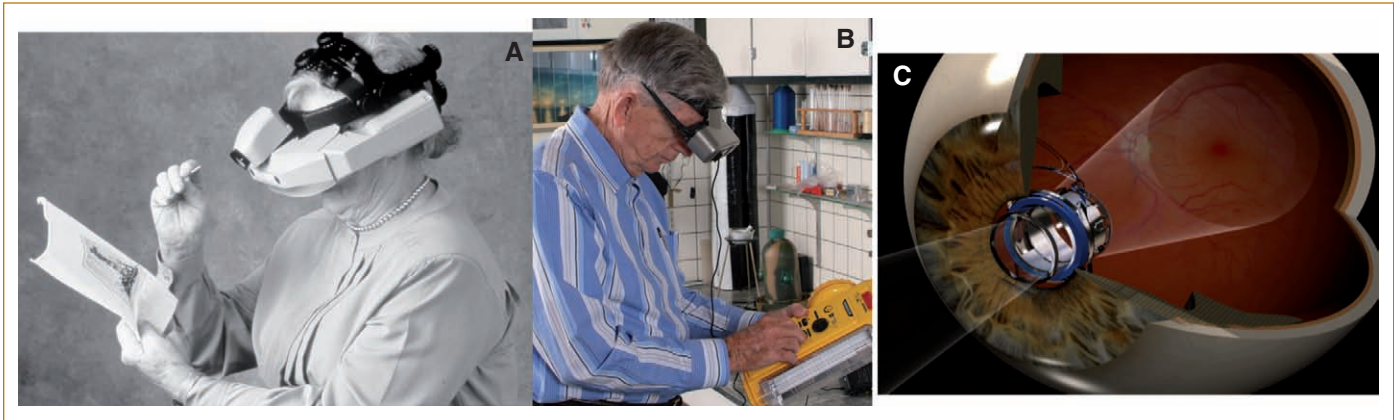

others are merely ideas. In the following sections, existing and prospective methods are presented.

#### Enhancing the Stimulus Through Optoelectronic and Optical Means

Most of these devices are based on a combination of optical and electronic image-enhancement techniques. Their common principle of operation is to improve visibility of the image to the diseased retina, through magnification, contrast and/or color enhancement, and filtering or feature extraction. Early incarnations, such as the low-vision enhancement system — LVES; no longer in production; see Fig. 69.4A and Massof (1999) — used optical magnification, zoom, automatic focus, and — for applications limited by available contrast, such as face recognition — analog image enhancement. These techniques have been adopted by more lightweight and cosmetically attractive video visors, such as the Jordy (Fig. 69.4B; Enhanced Vision Systems, Huntington Beach, CA) that enjoy considerable popularity among patients with severe visual impairment. More advanced image-processing techniques, such as digital feature enhancement and gaze-contingent remapping, will allow wearers to avoid losing crucial information in blind areas of the visual field. Such image-processing techniques have been implemented in the laboratory but are not currently available in portable format due to the need for eye tracking and real-time image transformations. However, with the rapidly increasing power of chip-based image-processing technology, such wearable optoelectronic vision enhancers cannot be far off. Another limitation of current versions is the product of field of view and angular resolution, i.e., the number of pixels across the screen. Commercially available systems have standard video/VGA resolution, but this is likely to increase sharply with the wider availability of high-resolution video camera and display formats (e.g., HDTV). Similarly, compactness and color representation will be improved as smaller, lighter, and more luminous flat panel displays become available.

A useful property of the cameras in portable video visors is their built-in automatic gain control (AGC), resulting in constant internal image brightness over a wide range of environmental illumination levels. Among other properties, this makes the image-acquisition and -processing stages of these systems highly suitable as sensors and preprocessors, respectively, for prosthetic and tissue-based image enhancement systems.

Incidentally, many optical systems increase the visibility of the stimulus. One of the latest, aimed at patients with a large central scotoma (blind spot) in both eyes due to advanced AMD, uses an implantable miniature telescope (IMT<sup>TM</sup>, Fig. 69.4C; VisionCare Ophthalmic Technologies, Saratoga, CA), placed behind the iris in the location of the crystalline lens. It provides one eye with a magnified view of the central visual field, while the other eye is not implanted, to preserve the wide peripheral view of the fellow eye.

**FIG. 69.4.** (A) The low-vision enhancement system (LVES), developed at the Johns Hopkins University's Lions Vision Center, with support from NASA and the Department of Veterans Affairs, is a characteristic example of optoelectronic vision-enhancement systems. This system features binocular orientation cameras, a centrally placed 1.5–10 $\times$  zoom camera with automatic focus, and a binocular projection path with 36 $^{\circ}$   $\times$  48 $^{\circ}$  field of view and built-in refractive correction and alignment for the wearer. (B) The Jordy video visor has a narrower field of view but is much lighter, thanks to its LCD screens, and has a full color display. Photo courtesy of Enhanced Vision Systems. (C) The Implantable Miniature Telescope (IMT<sup>TM</sup>) provides monocular 3 $\times$  magnification, to benefit patients with large central scotomas. Diagram courtesy of VisionCare Ophthalmic Technologies.

Following an adaptation and rehabilitation training period of three to six months, most wearers have no difficulty switching between the magnified view in the implanted eye and the unenhanced view in the fellow eye. Note that this is a true prosthetic device, since it is permanent.

### Visual Prostheses Based on Electrical Tissue Stimulation

As was already mentioned, retinas with severe degeneration of the sensor layer retain high numbers of secondary cells. In analogy with the principle of operation of the cochlear prosthesis, i.e., restoring limited hearing through stimulation of spiral ganglion cells in the cochlea (Clark *et al.*, 1990), this provides the opportunity to convey pixelized images to the degenerated retina by a prosthetic device stimulating remaining secondary cells with a two-dimensional array of microelectrodes, not unlike the rastered images provided by a stadium scoreboard (Dagnelie and Massof, 1996). From an engineering point of view, one can envisage a range of possible approaches (stimulation electrodes under vs. over the retina; fully integrated photo-sensor, image-processor and -stimulator systems vs. external image capture and processing linked to an intraocular stimulating matrix, to name a few) but also a host of questions concerning biocompatibility, signal processing, and power management.

The most pressing question regarding the feasibility of conveying visual imagery to patients blind from retinal degeneration has been answered affirmatively. In a series of experiments started at Duke University in 1992, continued from 1993 until 2000 at Johns Hopkins, and since then confirmed through similar experiments at Harvard University and in several German university clinics, volunteers

with end-stage RP — whose remaining vision was limited to, at best, light perception — as well as several patients with advanced AMD have participated in tests where, during a surgical procedure under local anesthesia, the inner surface of the retina was electrically stimulated with small and brief biphasic current pulses applied through a single electrode or multiple electrodes (Humayun *et al.*, 1999b; Rizzo *et al.*, 2003; Hornig *et al.*, 2005). Among the most salient findings are the subjects' ability to see small punctate light flashes (phosphenes), whose perceived location corresponds exactly to that of the stimulation, and the ability to see simple patterns of multiple phosphenes when multiple electrodes are activated simultaneously. Stimulation at rates greater than 40–60 pulses per second is perceived as continuous stimulation, and perceived stimulus intensity increases with pulse duration and amplitude as well as repetition rate. Independent tests in blind volunteers and in amphibian retina (Greenberg, 1999) have demonstrated that stimulus pulses 1 ms or longer in duration preferentially stimulate the (deeper) bipolar cells rather than the (more superficial) RGCs.

Over the past several years, research in this field has moved from acute experiments to chronic implant models, and academic research has joined forces with start-up companies and in some cases government labs to develop dedicated technologies enabling chronic implants. A good example is the relocation of the implant group formerly at Johns Hopkins University to the Doheny Retina Institute at the University of Southern California, the founding of Second Sight Medical Products LLC (Sylmar, CA) as a corporate partner, and the collaboration of these two entities with laboratories at state universities (e.g., UC Santa Cruz and UC Berkeley) and in the U.S. Department of Energy

(E) Silicon multielectrode designed by Normann *et al.* (1996) for penetrating stimulation of the visual cortex or retina. Interelectrode distances between 200 and 400  $\mu\text{m}$  can be manufactured. The 1- to 2-mm-long electrode shafts are insulated, and the tips can be metallized with Pt black or other suitable metals. Image courtesy of Richard A. Normann, Ph.D., University of Utah.

(Oak Ridge, Sandia, Livermore). A sample product of this collaboration is the chipset (RF encoder/transmitter and decoder/demultiplexer/drivers) developed at UCSC to control an intraocular electrode array (Fig. 69.5A). Such devices are currently being tested in experimental animals with naturally occurring retinal degenerations.

At the present time, several other groups are pursuing intraocular prosthetic devices, in two variants: subretinal-stimulating photodiode arrays, and epiretinal-stimulating electrode arrays with external image capture and preprocessing. The latter, the more common prosthesis type, is being pursued by two groups in the United States — USC/Second Sight (Humayun *et al.*, 2003) and Harvard/MIT (Rizzo *et al.*, 2003) — and by two groups in Germany: IIP Technologies (2006) (Fig. 69.5B; IIP Technologies, 2006) and a consortium of German universities (Walter, 2006). The USC/Second Sight group has performed six 16-electrode implants based on cochlear implant technology, and all four groups are preparing prototypes with 50 or more electrodes and wireless transmission to the freely moving eye; the IIP group was the first to perform two such implants since

late 2005. A number of other groups in the United States, Germany, Switzerland, Japan, Korea, and Australia are working with similar implant designs. Some of these groups seek to stimulate the retina from outside the eyeball, to avoid the risk associated with retinal surgery, while accepting the reduced resolution inherent in the greater separation between electrodes and target cells. Others are experimenting with penetrating electrodes through the scleral wall of the eye, in order to bring the stimulus charge as close as possible to the target cells.

The second type of retinal prosthesis, a subretinal chip that uses photovoltaic elements for image capture in the location once occupied by the native photoreceptors, is conceptually simpler but in practice more challenging. In the oldest version (Fig. 69.5C; Chow *et al.*, 2004) of the subretinal array, a 2-mm-diameter silicon chip with approximately 5000 small photodiode units is placed under the retina, near the vascular arcades, typically in patients retaining a small central area of functional photoreceptors. The photodiodes convert incident light into small DC electrical currents and, while the precise mechanism of action of

these currents remains to be elucidated, it appears that they lead to secondary release of neurotrophic factors in the surrounding retina, which in turn exert a beneficial effect on the remaining photoreceptors. This implant may therefore preserve some remaining vision, but it will not substitute an image by stimulating the secondary neurons.

An advanced version of the subretinal implant contains additional layers to provide signal amplification and pulse generation (Fig. 69.5D; Gekeler *et al.*, 2006). When placed at the level of the missing photoreceptor/RPE layer, it collects a sharp image of the outside world, mediated by the eye's optics, and generates localized electrical impulses that stimulate nearby (bipolar) cells in the overlying retina. Such an integrated prosthesis has great simplicity and elegance, but its feasibility hinges on three important premises: that nutrients and oxygen from the inner retinal vasculature will suffice to nourish the retina overlying the implant; that external energy can be provided to drive the amplifier and pulse generation stages; and that the heat generated by the implant's electronics can be safely dissipated into the underlying choroid without appreciably heating the overlying retina. Developers of such systems are concentrating on finding solutions for these problems as well as on the design of surgical methods to safely insert large arrays of such units under the retina (Volker *et al.*, 2004).

In addition to retinal stimulation, two other approaches to electrical stimulation of the visual system are being pursued. One of these, direct stimulation of optic nerve fibers through a set of electrodes mounted on the inside of a cuff placed around the optic nerve (Veraart *et al.*, 2003), is surgically less invasive than implantation of devices inside the eye, but it has the drawback that large numbers of fibers are stimulated simultaneously. Selective stimulation of individual optic nerve fibers will require microelectrode arrays much finer than those currently available and a sophisticated mapping system to establish the correspondence between visual field locations and individual electrodes.

The oldest attempts at vision restoration involved stimulation of the visual cortex through intracranial electrodes, controlled by external image-acquisition and signal-conditioning circuitry. Several decades ago, Brindley and Lewin (1968) took the first steps in this direction by implanting a set of electrodes over the visual cortex of a blind volunteer; the phosphenes described by this volunteer were similar to those elicited by intraocular stimulation. More recently, a team at the National Institute for Neurological Disorders and Stroke (NINDS) performed tests with over 30 electrodes penetrating the cortical surface (Schmidt *et al.*, 1996), and scientists at the University of Utah experimented with implantation of denser intracortical electrode arrays in cat and monkey visual cortex (Fig. 69.5E; Warren and Normann, 2005). The same group was also the first to perform simulation studies to establish minimum requirements for prosthetic vision (Cha *et al.*, 1992), an approach followed by several other groups (for a review, see Dagnelie,

2006). The cortical work that originated at NINDS is being continued through primate studies at the Illinois Institute of Technology (Bradley *et al.*, 2005), in preparation for future human implants.

The cortical prosthesis bypasses both retinal and optic nerve problems and might therefore be seen as a universal approach to vision restoration. Admittedly, it may be the only viable approach for patients whose inner retina and/or optic nerves have been destroyed by glaucoma or trauma. However, cortical stimulation requires complex surgery of an otherwise-healthy brain; moreover, the convoluted layout of the visual cortex complicates mapping of objects and locations in the outside world into a pixelized image that can be understood by the prosthesis wearer. Algorithms to establish such a map have been tested in primates (Bradley *et al.*, 2005) and through simulations in sighted volunteers (Dagnelie and Vogelstein, 1999) but thus far only for small sets of simulated phosphenes. The complexity of such algorithms for hundreds of phosphenes will be a significant burden on cortical implant research.

A final point of consideration for all visual prostheses for which the input image is acquired outside the eye is the altered role of eye movements. In natural vision, the intent of most eye movements is to bring an object of interest to the center of the retina, where it can be resolved with greater detail and receive directed attention. If a head-mounted or handheld camera is used for prosthetic image acquisition, movement of the camera rather than eye movements will recenter the image. To compensate for this difference, either a visual prosthesis can be equipped with eye movement monitoring and processing capability to shift the image accordingly, or the prosthesis wearer must learn to suppress eye movements as a means to acquire visual information, using camera (i.e., head or hand) movements instead.

A detailed review of developments in the areas of visual prosthesis development and simulation can be found in Dagnelie (2006).

### Retinal-Cell Transplantation

Cell transplantation in the neurosensory system can, in principle, restore function through two mechanisms: *rescue* of threatened cells (either by restoring a failing support system or through trophic factors secreted by the transplanted cells) and *replacement* of degenerating cells and *functional integration* of the transplanted cells into the host tissue. Both mechanisms may play a role in retinal cell transplantation, and the distinction is not always obvious, as will become clear.

There are two important distinctions in the choice of transplant modality. First, there is the distinction between *autologous* cells — harvested from the same individual who is to receive them, typically following amplification and/or differentiation in tissue culture — and *allografts* — harvested from a different donor, who is typically unaffected and immunologically matched. Second, the developmental

stage of the transplanted cells may range from pluripotent stem cells to organ-specific undifferentiated cells to postmitotic (e.g., photoreceptor precursor) cells. Since the range of possible approaches far exceeds the scope of this chapter, only major developments will be indicated; a recent review of stem cell approaches to retinal degeneration can be found in Young (2005).

Some important categories of retinal disease are mediated by loss of RPE function, and both transplantation of autologous pigment epithelium and allografts have shown success in rescuing photoreceptor function. In the RCS rat, rescue of photoreceptor function can be accomplished by replacement of the degenerating RPE with a wide range of transplants, from RPE xenografts (harvested in a different species) (McGill *et al.*, 2004) to autologous iris pigment epithelium (Semkova *et al.*, 2002). In human retinal disease, macular translocation surgery in AMD has demonstrated the feasibility of rescuing threatened vision by relocating the neural retina over a relatively healthy area of RPE (de Juan and Fujii, 2001). Immunologically mismatched RPE allografts and xenografts may not provide viable treatments in human retinal disease: Contrary to the neural retina, where immune response appears to be muted or absent, a slow inflammatory response to mismatched transplanted RPE tissue is commonly observed (Zhang and Bok, 1998).

Retinal diseases that originate in a photoreceptor-cell defect do not lend themselves to treatment with autologous cell transplantation, since the same defect is likely to plague the transplanted cells. Since the mid-1990s, transplants with cell suspensions and organized sheets containing mature photoreceptors or photoreceptor precursors (with or without RPE) have been used therapeutically, with varying degrees of claimed efficacy. In a light-damaged rat model, morphological evidence of synapse formation (del Cerro *et al.*, 1989) and behavioral evidence of regained function (DiLoreto *et al.*, 1996) were among the earliest indicators that transplanted photoreceptors may be capable of assuming visual function. More recent evidence in the same direction from other laboratories suggests that functional synapse formation is possible in some animal models, while in others a glial seal under the retina effectively inhibits integration of the transplanted tissue with the host retina (Seiler and Aramant, 2005). The mechanisms responsible for such widely different results remain to be elucidated but are most likely associated with varying patterns of reorganization occurring in response to different retinal degeneration genotypes (Jones and Marc, 2005).

Fetal tissue has thus far proven more successful than fully developed retina or stem cells in forming synaptic connections and retinal morphology resembling that of intact retina, and it has become the tissue of choice in most transplantation attempts. This tissue also carries a lower risk of rejection by the host immune system, at least in photoreceptor grafts; indeed, rejection does not appear to occur in rat or mouse photoreceptor transplantation (del Cerro *et al.*,

1997). Admittedly, some caution in extrapolating this finding to other species is warranted, for immune reactions in rodents tend to be less severe than in humans. The use of fetal tissue for research and transplantation purposes is subject to legal and ethical concerns in a number of countries, and this is an important reason for continued efforts to develop transplantation techniques that use adult donor tissue.

Preliminary attempts at retinal-cell transplantation in blind volunteers, performed primarily to demonstrate safety, have yielded mixed, and at best modest, results. Allografts of cultured RPE appear to provide protection to functional AMD through trophic factors, but in exudative AMD the graft is quickly overwhelmed by an inflammatory reaction (Gouras and Alverez, 1996). Photoreceptor transplants appear to convey an improvement in vision in some cases (Humayun *et al.*, 2000), but whether this is mediated by graft–host synapse formation or trophic support to the few remaining photoreceptors cannot be distinguished (del Cerro *et al.*, 2000).

The ciliary body in the human eye contains pluripotent stem cells that will, under appropriate conditions, differentiate into retinal neuron precursors (Trobepe *et al.*, 2000); hence, the potential for photoreceptor cell replacement from tissue culture does exist. At this time, however, any attempts to use bone marrow and retinal stem cells to replace degenerating photoreceptors in human patients through injection into the vitreous or subretinal space, as reported in the press and on the Internet, seem highly premature. It is unlikely that such attempts, without thorough research in animal models of retinal degeneration, will lead to effective and reliable vision restoration or even to long-term survival of the remaining photoreceptors.

## Optic Nerve Protection and Regeneration

Retinal ganglion cells (RGCs) behave as central nervous system neurons in their inability to recover from severe injury: RGCs whose axons are damaged by cutting or crushing the optic nerve undergo apoptosis within a few days following injury, although this particular mechanism of cell death may be restricted to certain classes of RGC (Kurimoto *et al.*, 2003). And while the axons of peripheral (motor or sensory) neurons can regenerate on surgical reconnection of nerve fascia, CNS neurons appear to lose plasticity once their original outgrowth during the organism's development is completed, due to changes in both their internal makeup and their environment. Oligodendrocytes that form the protective myelin sheath around optic nerve axons and astrocytes appear to play a major role in preventing axon regeneration following injury (Dezawa and Adachi-Usami, 2000). It has been since the 1980s, however, that this environment can be effectively modified: Cut optic nerve axons in rat and cat will not form new neurites in their natural optic nerve environment yet can be made to regenerate into a peripheral nerve graft and reach the superior colliculus

(Aguayo *et al.*, 1987; Vidal-Sanz *et al.*, 2002; Watanabe and Fukuda, 2002). Two basic steps are thus necessary for therapeutic intervention in advanced optic nerve disease to become a reality: protection of RGCs from apoptosis following severe damage to the optic nerve, and axon regeneration, including formation of functional connections at the thalamus and other midbrain structures.

Studies in the last few years have provided encouraging indications in both areas. Intravitreal injections of anti-apoptotic drugs and neurotrophic factors can limit the loss of RGCs and prolong the window for application of other therapeutic modalities (Watanabe and Fukuda, 2002). Most of these therapies are aimed at preserving the RGC soma so that it can sustain a partially damaged axon, but there is still a need for targeted therapies that can either repair damaged axons or stimulate new axon growth (Levin, 2005). Some progress is being made in stimulating axonal growth: A recent report identified oncomodulin as a factor that is particularly effective in promoting growth following optic-nerve crush (Yin *et al.*, 2006).

### Drug Delivery

Since 1995, the understanding of photoreceptor and RGC death has changed dramatically. While it was previously thought that these cells die because a functional part—the photoreceptor outer segment and the axon, respectively—becomes dysfunctional, both events are now widely understood to trigger cell death through apoptosis and similar mechanisms. Better understanding of these mechanisms has led to the search for pharmacological interventions that may prevent cell death.

The process of RGC degeneration following transection or crushing of the optic nerve can be halted, at least in animal models, with the use of neuroprotective agents such as neurotrophin-4/5 (NT-4/5; Sawai *et al.*, 1996). It turns out, however, that this protection has only a limited duration. Most RGCs die within two to four weeks, even with sustained administration of NT-4/5 (Clarke *et al.*, 1998). Various other neuroprotective strategies have been attempted in animal models, but their long-term efficacy as well as the feasibility of long-term delivery near the threatened site remain to be demonstrated.

In the case of photoreceptor degenerations, a variety of nerve growth factors and neuroprotective agents have been used, both *in vitro* and in animal studies, and several of these have shown promise (LaVail *et al.*, 1998). What remains to be worked out for most of these substances is the optimal delivery route. Systemic administration is not an option, since many of these agents do not easily pass the blood-retina barrier and/or have unwanted systemic side effects. Administration as an eye drop is not effective, because the active substance would need to diffuse through the cornea or sclera, and most of it would be washed away in the tear film. Repeated injection into the vitreous is unattractive to the patient, and it is not clear how long the

active substance would persist in the eye and reach the outer retina.

Three relatively recent delivery techniques have all been successfully applied to ocular drugs in recent years: delivery by macromolecules, slow-release implants, and encapsulated-cell technology. The first of these approaches caused a revolution in the treatment of exudative AMD about 10 years ago, now widely known as photodynamic therapy (PDT): Liposomes with an embedded antiangiogenic substance (verteporfin) are injected into the bloodstream, and irradiation of the retina with a low-energy laser beam is used to release verteporfin in the choroidal space under the retina. The resulting oxygen free radicals attack vascular endothelial cells and stop angiogenesis (Asrani *et al.*, 1997). Unfortunately, this endothelial-cell cytotoxicity is not an effective long-term treatment, so, following the demonstrated safety of locally administered vascular endothelial growth factor (VEGF) inhibitors, PDT has over the last few years been replaced as the treatment of choice by intravitreal injections of such substances (Macugen, Avastin, and Lucentis; Rosenfeld *et al.*, 2006), even though injections have to be repeated once every six weeks. The longer-term outlook for these substances is very good. They can be embedded in poly(lactic-glycolic) acid (PLGA) microspheres to create slow-release implants that could be inserted into the eye through a small incision and attached to its inside wall, or they may even be effective when placed on the outside of the eyeball (Zhou and Wang, 2006). The third delivery method, encapsulated-cell technology (ECT), is elegantly exemplified by the NT-501-permeable-membrane delivery system developed by Neurotech SA (Lincoln, RI). When loaded with a transgenic cell line producing ciliary neurotrophic factor (CNTF) and implanted in the vitreous cavity, it will release a flow of CNTF for many months (Thanos *et al.*, 2004). Applications are sought in the area of photoreceptor protection in retinal degenerations; a phase I trial in retinitis pigmentosa has been completed successfully (Sieving *et al.*, 2006), and efficacy trials in AMD and RP were being planned for 2007.

In some diseases, even the simplest of drug delivery may be effective. In retinal ischemia, just as for other vascular blockages, clotbuster drugs, such as tissue plasminogen activator, can be intravenously injected. If this is done soon (hours or even days) after the ischemic event, much of the damage may be prevented; experimental therapy with these drugs has had promising results (Elman *et al.*, 2001).

### Genetic Interventions

Delivery issues also play a role in the introduction of new genes into the degenerating retina. Most retinal degenerations are genetic in nature, either inherited from one or both parents or caused by a new mutation. The premise of gene therapy is that intervention at an early stage may restore normal function to the cell and prevent the degeneration

process that might otherwise ensue. Several strategies are needed to combat inherited retinal degenerations.

- In recessively inherited diseases, both copies of a gene are defective, and introduction of a third copy may be sufficient to achieve adequate production of a functional protein to replace the defective one encoded by the mutated gene. An inactivated (retro)virus is used to introduce a healthy copy of the gene. Following a number of demonstrations of successful gene transfection into RPE cells and photoreceptors *in vitro* and feasibility studies in rodents, a highly publicized study of vision rescue in a canine model of Leber's congenital amaurosis (Acland *et al.*, 2001) provided proof that gene therapy for some human retinal degenerations may soon be a reality
- In X-linked disease, males carry only one copy of the X-chromosome, including the defective gene; here, too, introduction of a healthy copy of the gene may be enough to achieve normal function.
- In dominant disease, a single bad copy of the gene suffices to poison the delicate balance of the cellular machinery or, at the very least, to prevent its proper function. To reduce or prevent this, a therapeutic intervention must block a step along the transcription pathway from the defective gene to its product protein but not inhibit expression of the good copy of the gene; a gene for such a blocking agent could, in principle, permanently neutralize the defect. This technique has been used in a transgenic rat model, using ribozymes to destroy mRNA produced by the P23H mutant gene defect responsible for one form of autosomal dominant RP (Drenser *et al.*, 1998). In a rat model with a naturally occurring degeneration, a gene for ribozyme production was successfully introduced into photoreceptors and proved effective even when introduced at a time when many photoreceptors had already succumbed to the effect of the defective rhodopsin gene (LaVail *et al.*, 2000), which bodes well for therapeutic interventions in dominant RP. These forms of RP tend to preserve substantial levels of vision into middle age, and this remaining vision might thus be rescued.
- An entirely separate class of retinal degenerations, typically asymptomatic until middle age and often associated with multisystem disease, is caused by mutations of the maternally inherited mitochondrial DNA, responsible primarily for cellular energy supply. Mitochondrial DNA has multiple copies, and it remains unclear whether single or multiple copies are responsible for these disorders. Moreover, the mitochondrial DNA does not lend itself to normal viral transfection techniques, which adds a level of complexity to potential gene therapeutic approaches. Recent reports suggest that proteins may be used to deliver expression-blocking factors or new functional genes into the mitochondrial milieu (Khan and Bennett, 2004).

Vision-related gene therapy research is concentrated around RP, Stargardt macular dystrophy, and related diseases with known inheritance patterns. Due to the multiple genes that can lead to these disorders and the enormous number of specific mutations that have already been identified, many gene therapeutic variants will be needed to address a substantial proportion of these disorders. This is an extremely active area of research; excellent reviews can be found in Delyfer *et al.* (2004) and Dinculescu *et al.* (2005),

Still, this means that a true cure may become available for these retinal degenerations. AMD and optic nerve diseases like glaucoma and ischemia, on the other hand, have no known genetic causes, though some genes associated with predisposition for such diseases have been identified. Genetic interventions may assist in preventing some forms of these diseases, but the prospects of other therapeutic approaches are more promising than those of gene therapy.

#### IV. EMERGING APPLICATION AREAS FOR ENGINEERED CELLS AND TISSUES

Of the current approaches to vision enhancement considered earlier, strictly speaking only the use of stem and transgenic cells falls within the realm of tissue engineering. The complexity of ocular structures such as the retina and optic nerve poses daunting challenges to anyone seeking to re-create their function. While this may explain the lag in progress as compared to other organ systems, it should not keep researchers working to restore vision from drawing on the remarkable progress of tissue-engineering approaches. We next briefly consider four application areas, corresponding to the aforementioned three processing stages in the early visual system where severe vision loss may occur and the supporting retinal infrastructure.

##### Photosensitive Structures

Current efforts in the areas of retinal-cell transplantation and intraocular prosthesis design, while promising, are in no way guaranteed to lead to reliable — i.e., long-term stable — restoration of useful (let alone high-quality) vision. As was explained earlier, each of the approaches currently being explored has inherent drawbacks: Epiretinal electrode arrays require external image acquisition and preprocessing, which may necessitate real-time eye movement tracking and compensation. Subretinal implants may cause atrophy of the overlying retina and are limited by the low yield of semiconductor photoelectric conversion, the need for signal amplification and thus external energy supply, and considerable heat production. Both implant types may be limited in resolution to ambulatory vision due to the 100- to 200- $\mu\text{m}$  distance separating the electrodes from the target cells. As a rule of thumb, resolution in the underlying tissue will be no better than this distance. Retinal cell transplanta-

**FIG. 69.6.** Pillar electrodes penetrating into the middle of the inner nuclear layer of degenerated retina. **(A)** Electron micrograph of an array having pillars of 10  $\mu\text{m}$  in diameter and 70  $\mu\text{m}$  in height. **(B)** Histology of the RCS rat retina with a pillar array six weeks after implantation. **(C)** Schematic of a retinal prosthetic: retinal cells in the inner nuclear layer stimulated by pulsed electric fields emanating from the exposed tops of the pillars. Images provided by Daniel Palanker, Ph.D., Stanford University.

tion efforts are likely to be limited by the spotty record of transplanted cells in making functional contacts with the native inner retinal circuitry. And all three approaches are limited by microneuroma formation, destroying the functional diversity of the inner retina and limiting its resolution to 50–100  $\mu\text{m}$ , i.e., at best 20/200 visual acuity — legal blindness.

For improved retinal prosthetics, it may be possible to develop electrodes that make more intimate contact with the target cells. If successful, this would improve resolution to the limit imposed by the repatterned inner retinal neuronal circuitry. One can envisage such a penetrating array as the Normann microelectrode in Fig. 69.5E, but the damage such an array might do to the delicate microphysiology of the retina is a distinct disadvantage. As an alternative, one might envisage inserting or growing, *in situ*, an array of parallel neurites. These might branch out of cells grown on the surface of implanted stimulating chips, penetrating the retina until they reach a specific target environment, e.g., the inner nuclear layer, where they would make synaptic contacts with the native cell population; these neurites would act as “tube electrodes,” releasing either electrical charge or a neurotransmitter that would activate the target cells. An alternative approach would be an electrode structure that stimulates nearby retinal cells to form new neurites, spurred on by favorable growth conditions and a coating on the implant. Such coatings promoting cell growth, formed by microcontact printing, are under investigation (Mehenti *et al.*, 2006).

The distance between implant and target cells could also be reduced by enticing native retinal cells to migrate toward the electrode surface, adding a new twist to the cell migration seen in naturally occurring retinal repatterning (Jones and Marc, 2005). Such approaches are not as far-fetched as they may sound. Several groups are experiment-

ing with surface modifications on semiconductor chips that will allow cells to adhere to these surfaces and be activated by neurotransmitters (Atencia and Beebe, 2005), while researchers at Stanford have reported the tendency of retinal neurons to migrate through a perforated membrane placed under the photoreceptor layer (Fig. 69.6; Palanker *et al.*, 2004). Combinations of such technologies may lead to improved implant–tissue interfaces.

A fundamentally different approach to improving (sub)retinal prostheses may be the use of high-yield photo-conversion systems. Such high-yield conversions are known to be performed by Photosystem I (PSI), a macromolecule present in the membrane of thylakoids, which can be found inside the chloroplasts that give the green color to plant leaves and algae. Recent experiments with thylakoids (J. W. Lee *et al.*, 1996) have shown that it is possible to anchor these structures onto a metal surface and use them as miniature photovoltaic elements. I. Lee *et al.* (1997) have also demonstrated that it is possible chemically to modify thylakoid surface membranes to create charge displacement in a specific direction. Kuritz *et al.* (2005) demonstrated the ability of PSI to impart photosensitive polarization and  $\text{Ca}^{2+}$  ion movement to retinoblastoma cells in tissue culture, as a first example of cellular engineering that may eventually lead to artificial photoreceptors.

The engineering successes of thylakoids and PSI open the opportunity to create cells that assume a dipole charge distribution or, with the help of some form of intracellular electronics, produce a biphasic pulse between the poles; in a subsequent stage of development, automatic gain control could be incorporated as a limited form of light/dark adaptation. If these cells can be made to attach to the outer retinal layers or to migrate into the inner nuclear layer, one could achieve microscopic local current sources with sufficient conversion efficiency to ensure vision at a broad range of

(day)light levels. To achieve true night vision, an external device, such as a night vision scope, could be used.

Note that in this idealized situation, the synthetic photoreceptors might be small and sensitive enough to provide good vision without external image preprocessing (e.g., magnification and contrast/edge enhancement). It is to be expected that preliminary forms of such light-sensing units will be neither small nor sensitive enough to provide the dynamic range and resolution required; at this intermediate solution level, external image processing with an advanced portable low-vision visor would be a necessary complement to this intraocular light-conversion array.

### Outer Retinal-Cell Transplantation

Despite almost two decades of careful investigation, reliable and widespread formation of synapses between transplanted photoreceptor precursors and native inner retinal cells — the gold standard for full integration of the transplanted cells into the host retina — remains elusive. Also, the effects of the host immune response on graft survival — especially of transplanted RPE — cannot be ignored, even if it appears to be mild, and this host reaction will have to be effectively controlled without long-term systemic immune suppression. Both areas can profit from tissue-engineering approaches. A complex set of conditions — cells in the proper stage of development, properly matched to the host retina, and spurred on by a proper combination of neuroprotective and neurotrophic modifications to the host environment — needs to be met for successful graft–host integration. Recent reports indicate that even widely held beliefs regarding the proper developmental stage of the transplanted cells may need to be revisited. In a mouse model, early postnatal photoreceptors showed widespread synapse formation with native retinal cells (Ali *et al.*, 2006), whereas most previous research has been directed at the use of postmitotic photoreceptor precursors in a much earlier stage of development.

Even if the cell population affected by the primary degeneration process is successfully replaced, secondary degeneration stages — of RPE cells in photoreceptor degenerative disease and of photoreceptors in RPE degeneration — may still prevent restoration of visual function. This problem can be addressed adequately only by performing a combined graft of RPE and photoreceptors, presumably prepared in a tissue culture environment and stimulated toward integration through a carefully tuned combination of neuroprotective and neurotrophic factors. Culturing stem cells or differentiated cell lines might allow the creation of heterogeneous structures such as RPE/photoreceptor double-sheets. Culture conditions and the growth stage of these sheets should be modulated to prepare the cells for integration with the host retina. In order to provide sufficient structural support to these fragile sheets during growth and transplantation, a resorbable polymer layer could be used as a substrate.

### Cell Matrices Supporting Axonal Regrowth

Cell culture conditions and retinal integration alone will not be sufficient in the case of ganglion cell transplantation with the objective of repopulating the optic nerve with axons carrying visual information to the brain. As discussed earlier, this will require the (re)creation of conditions favorable for axonal growth over distances of many centimeters and the ability of sprouting axons to contact target cells with the correct retinotopic mapping. This feat is accomplished effortlessly by RGC axons in the developing embryo, but to recreate the conditions for this to occur in an adult organism will be a considerable challenge.

As was noted earlier, an RGC axon damaged by glaucoma, optic nerve disease, or injury can only form new neurites under optimal environmental conditions, essentially mimicking those in a developing organism. At the same time, neuroprotective factors are required to sustain the RGC long enough for the axon to assume this support function. If the glaucoma diagnosis is made early and safe and effective neuroprotective agents become available, it may be possible to save most of the threatened axons and thus spare most RGCs and the patient's vision. In practice, however, many axons may have been lost by the time the diagnosis is made, and protection of the cell somata and stimulation of axon regrowth become the treatment objectives (Quigley and Iglesias, 2004). The experimental conditions employed thus far, using peripheral nerve sheaths to create a substrate for axonal regrowth, are less than ideal, because they do not provide an integrated environment in which regrowing axons combine with intact remaining axons and in which protection of the threatened RGCs is built into the environment. This is a very active field of research, offering great potential for tissue-engineering approaches, and one may expect such approaches to play a major role in achieving these objectives. Understanding the necessary conditions to create an integrated environment for axonal regrowth and creating novel synthetic materials to provide these conditions should provide wonderful challenges to tissue engineers.

One approach to such an integrated solution might be that engineered cells could be grown *in situ*, as a loose skeleton of supporting tissue, to follow the course of the optic nerve to the chiasm and optic tract; these cells would be programmed to exude the necessary factors promoting axon growth and RGC protection. Alternatively, it might be possible to modify the normal environment of the optic nerve (temporarily) to allow or even stimulate axonal growth. Assuming that it would be possible to guide outgrowing axons through the optic chiasm toward the appropriate structures and retinotopic projections in the midbrain, RGCs may restore their connections to the target cells and resume functional visual processing.

## Repopulating Ischemic or Diabetic Retina

As mentioned earlier, new capillaries — formed under the influence of an angiogenic tissue response — tend to be poorly organized and fragile, causing leakage and thus a great deal of damage to the already stressed retinal tissue. Therefore, the prospects of restoring vision in such retinal areas are, at the present time, poor.

This may change, however, if cell populations can be grown *in vitro* and introduced into the retina under physiological conditions mimicking those during embryonal development. In that case the formation of new blood vessels could follow a more orderly pattern, and implanted cells would have a much better chance at forming functional connections. Whether and when it will be possible to re-create embryonal conditions and grow such integrated retinal tissue required to restore vision to an ischemic portion of the retina, from RPE to RGC axons, is difficult to predict. It is a challenge whose magnitude exceeds that of RPE/photoreceptor transplants, functional stimulation of inner retinal cells, and RGC protection/axonal regrowth combined.

## V. CONCLUSION: TOWARD 20/20 VISION

The potential applications of tissue engineering sketched in the previous sections pose enormous chal-

lenges, well exceeding the competency of any single group or institution. Concerted research efforts by multidisciplinary groups may allow the implementation of the complex systems required to restore and enhance vision. As researchers improve, on the one hand, their fundamental understanding of processes such as photoconversion, graft integration, immune regulation, and neuroprotection and, on the other, the engineering ability to control tissue properties and neurite growth, both *in vitro* and *in situ*, crude but functional vision restoration at the RPE/photoreceptor level and at the RGC level will advance to the level of experimental and even clinical therapy. Integration of all these areas to re-create the full range of retinal processing is a much more distant goal, for which the header of this section may well be too ambitious.

To accomplish any of these forms of vision restoration, however, funding mechanisms for multidisciplinary research and interest from the corporate sector will have to rise well beyond their current levels. While the number of severely visually impaired individuals and the economic impact of vision restoration alone may not justify that these approaches receive priority over treatment of life-threatening conditions, the investment required is relatively modest, and the improvement in quality of life for (nearly) blind patients can be very significant.

IV. Dental-Tissue Regeneration  
V. Conclusions  
VI. References

### I. INTRODUCTION

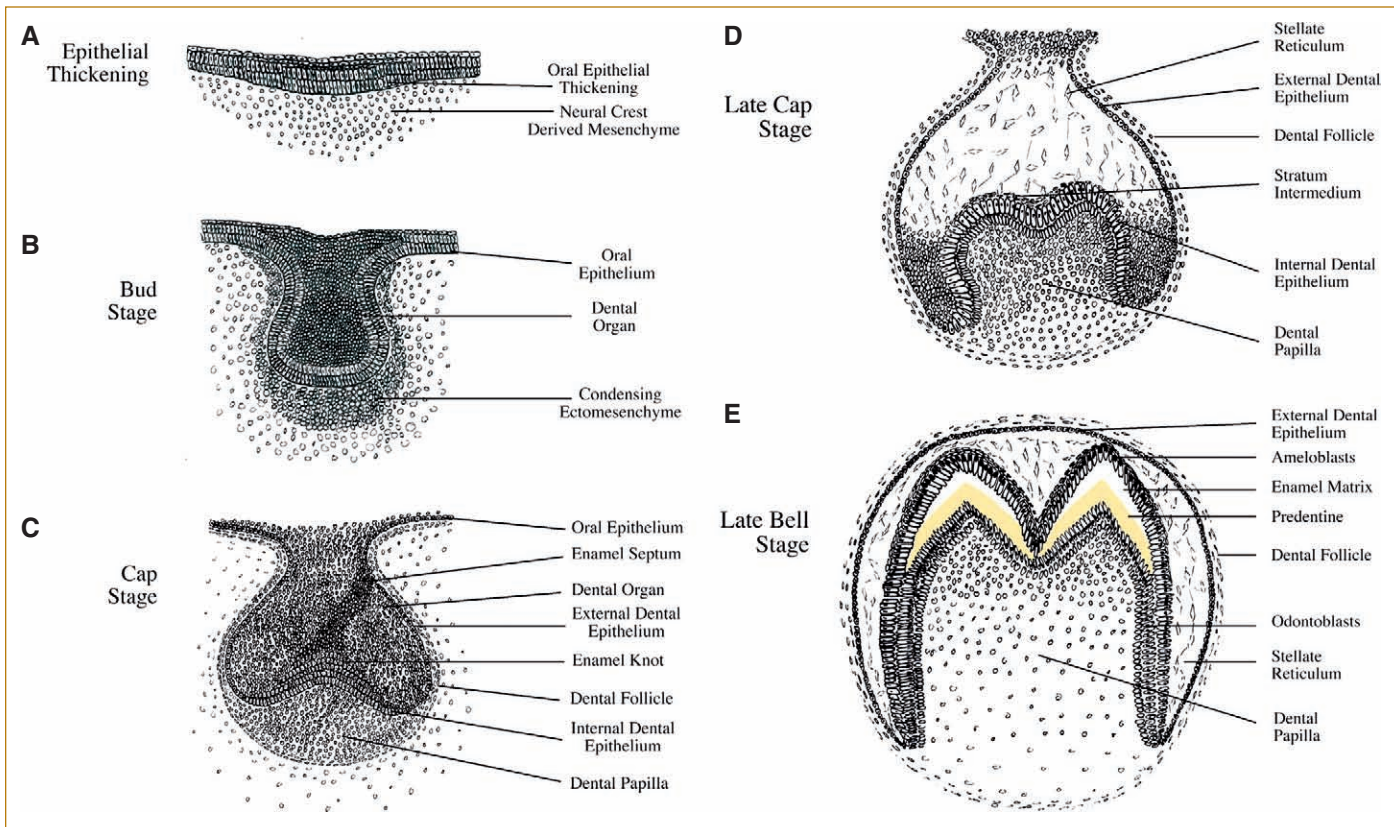

Teeth might not at first seem an obvious organ to develop biological methods for replacement or repair. Teeth are nonessential organs, and modern dental treatments enable most dental problems to be treated using traditional nonbiological approaches. Teeth do, however, offer unique opportunities to develop tissue-engineering-based approaches on an organ that is not only easily accessible and non-life-threatening but one where there are very large patient numbers and a significant clinical problem. The challenges of developing methods needed to restore and repair complex organs are immense, but the biggest challenge will be the testing of any such organs on patients. Patients requiring repair or replacement of major internal organs (heart, liver, lungs, pancreas, etc.) are by definition likely to have a serious illness. Access to these organs requires major surgery; should the treatment fail, the consequences will be severe and life threatening. Teeth do not present any such problems and thus provide an opportunity for the proof of concept to be tested safely, with little chance of danger to the patients.

Although there are an increasing number of alternative treatments in dentistry, most are nonbiological and many are based on techniques that have been practiced for thousands of years. Dental implants, for example, involve the replacement of missing teeth with metal rods that are

screwed into holes drilled into the jawbone. The practice of replacing missing teeth with metal implants can be traced back to the ancient Romans and Egyptians (Crubez *et al.*, 1998; Westbroek and Martin, 1998). The number of dental implants is increasing each year, and thus there is a need to develop new biologically based approaches. Similarly, many tooth fillings still use mercury-based amalgams, and the possibility that repair of dental hard tissues (dentine and enamel) might involve the use of cells to remineralize the damage to teeth naturally is an exciting prospect. This chapter explores the current status of research directed toward whole-tooth replacement and repair of dental disease.

### II. TOOTH DEVELOPMENT

Teeth are ectodermal appendages (hair, sweat glands, salivary glands, etc.) that develop from an increasingly well-understood series of reciprocal epithelial mesenchymal interactions (Figs. 70.1 and 70.2). In mammals, these interactions take place in the developing oral cavity between the oral ectoderm (epithelium) and cranial neural crest–derived mesenchyme (ectomesenchyme). The cellular origins of the signals that initiate tooth development have been the subject of much controversy over the years, but modern molecular and animal techniques have confirmed that the oral (pre-dental) epithelium is the source of the signals that initiate

**FIG. 70.1.** Drawings of histological sections of mammalian first-molar-tooth development.

odontogenesis (reviewed in Thesleff and Sharpe 1997; Tucker and Sharpe, 2004). Recombination experiments between dental cells and nondental cells have identified temporal changes in the direction of inductive signals. Following the initial epithelial-to-mesenchymal inductive signals, a long series of temporally and spatially controlled exchange of signals governs each step in the increasingly complex development of a tooth. With the exception of the nerve supply, all the cells of a mature tooth originate from the oral epithelium and ectomesenchyme. The epithelial cells form only one functional cell type, the ameloblasts that are responsible for enamel formation. All of the other cell types, including the odontoblasts that are responsible for dentine formation, periodontal ligament cells, the pulp cells, etc., are derived from ectomesenchyme. The ability of ectomesenchyme to differentiate into these different cell types illustrates the stem cell-like properties of these cells. Classic recombination experiments in the 1980s established that non-neural crest cell populations of mesenchymal cells cannot respond to tooth-inductive signals, and, more recently, the requirement for dental mesenchymal cells to have stem cell properties has been established (see later). An understanding of the properties of predental epithelium, mesenchymal cells, and the interactions and molecules involved is the key to developing biological approaches for replacement and repair.

### III. WHOLE TOOTH-TISSUE ENGINEERING

#### Stem Cell-Based Tissue Engineering of Teeth

The aim of this approach is to reproduce an embryonic tooth primordium from cultured epithelium and mesenchymal cells. Since it is established that embryonic tooth primordia are able to continue their embryonic development in ectopic adult sites such as the kidney, the expectation is that the artificial primordia will develop into teeth following implantation as tooth rudiments into the adult mouth. Thus, rather than a metal dental implant, a cell-based biological implant will be transplanted. Since the ectomesenchymal cells of the tooth primordium form the majority of tooth cells and regulate tooth shape, it is finding replacements for these cells that has been the main initial focus. The early inductive interactions that take place *in vivo* show that the mesenchymal cells must have stem cell-like properties. Cultured populations of stem cells have thus been used to replace these ectomesenchymal cells in recombinant tooth explants. Cultures of mouse ES and neural and adult bone marrow cells were aggregated to form a semi-solid mass, on which embryonic oral epithelium was placed (Ohazama *et al.*, 2004). When cultured for two to three days, the initiation of an odontogenic response in the stem cell “mesenchyme” cells could be visualized with molecular markers. Transfer of the explants in the kidney capsules of

**FIG. 70.2.** Diagrammatic representation of two methods currently being explored for producing biological tooth replacement. Figure kindly drawn by Rachel Sartaj.

adult mice was then used to assay for tooth formation. “Bio-teeth” explants made with mesenchyme derived from ES and neural stem cells proved difficult to transfer intact into kidneys. Explants made from adult bone marrow stromal cells, however, were substantially more robust and survived transfer. Following incubation of explants in kidneys for 10–14 days, clearly identifiable tooth crowns were formed, surrounded by bone. By using cells from genetically distinct transgenic mouse lines (GFP, LacZ), the stem cell origins of dental mesenchyme cells and bone cells could be confirmed. Cells derived from adult bone marrow stromal were thus capable of contributing to tooth formation in a way identical to ectomesenchyme cells. Moreover, development of the tooth crowns appeared to follow the normal pathway of embryogenesis, with the formation of new bone completely surrounding the tooth. New bone formation is an essential (but often overlooked) component of biotooth formation. A biotooth has to be able to anchor itself to the jaw

bone with roots and a periodontal ligament. Concomitant bone formation must therefore occur during tooth development. Although the oral epithelium gives rise to only one major functional cell type in teeth (the ameloblasts) and these cells are lost from mature teeth, the oral epithelium is required for tooth primordia induction and further development. Sources of epithelium that can induce and participate in biotooth formation thus need to be identified. Currently, several different potential sources are under investigation (Odontis Ltd. unpublished information).

### Bio-teeth from Cell-Seeded Scaffolds

In the early 1950s, Shirley Glasstone-Hughes demonstrated that when early-stage embryonic tooth primordia are physically divided into two halves, each half develops into a normal-size tooth (Glasstone-Hughes, 1952). This pioneering experiment demonstrated the developmental plasticity and regenerative capacity of embryonic tooth germs. This

regenerative capacity has been exploited to devise a simple, biodegradable scaffold-based approach to biotooth generation. The early pioneering work of Vacanti and coworkers on the use of biodegradable scaffolds to act as supports for guided tissue regeneration has provided the basis for using the reorganizational properties of dental primordia cells to reform teeth *in vitro* (Cao *et al.*, 1997). The basic principle is to create scaffolds in the shape of the tooth required. These are then seeded with cells isolated following dissociation of third-molar-tooth germs. Third molars, or wisdom teeth, erupt late in human development and thus in young adults are present as dormant primordia. Both pig and rat third-molar primordia have been used with essentially the same procedure, utilizing biodegradable polymer scaffolds (Young *et al.*, 2002; Duailibi *et al.*, 2004; Honda *et al.*, 2005). Cells from third molars at the late bud stage of development were dissociated by incubation with collagenase and dispase, and the cells were then either seeded directly into scaffolds or cultured for up to six days in DMEM plus 10% FBS before seeding. The scaffolds were composed of polyglycolate/poly-L-lactate and poly-L-lactate-co-glycolide prepared using polyvinyl/sioxane and molded into the shape of human incisors and molars. For pig cells, scaffolds of  $1 \times 0.5 \times 0.5$  cm were used; whereas for rat cells, rectangular scaffolds of  $1 \times 5 \times 5$  mm were used. Scaffolds containing seeded cells were surgically implanted into the omentum of rats (athymic rats for pig cells) and left for 12–30 weeks. Histological sectioning of the explants revealed the formation of tiny tooth-like structures. The structures were between 1 and 2 mm in size and showed many of the features of molar-tooth crowns, including differentiation of ameloblasts and odontoblasts. Experiments using pig cells detected the tooth-like structures after 20 weeks, whereas with rat cells these formed after 12 weeks. In all cases, the shapes of the toothlets formed were independent of the shape of the scaffold, and, unlike natural tooth formation, no bone was formed in association with the teeth. Based on the previous results of Glasstone-Hughes, the most likely explanation for these results is one of reorganization rather than *de novo* formation. The small size of the teeth indicates that small numbers of dental epithelium and mesenchyme cells reassociated to form tooth germs. The fact that cells could be cultured for up to six days indicates that either the epithelial and/or mesenchymal cells are able to retain their odontogenic properties or the possibility exists that stem cells were present in the cell populations, but this remains to be demonstrated. A functional biotooth must be able to form roots; in order to do this, new bone must form at the same time as the tooth. In the scaffold approach, no new bone is formed. In order to address this, scaffold toothlike structures have been generated together with bone implants produced from osteoblasts induced from bone marrow progenitor cells seeded onto polyglycolide-co-lactide-fused wafer scaffolds (Young *et al.*, 2005). The codevelopment of bone and tooth-like structures permitted the early formation of roots

and thus demonstrated the possibility of utilizing a form of hybrid tooth/bone-tissue-engineering approach.

The phenomenon of reorganization of dental primordia cells into teeth has been investigated in detail by Lesot and colleagues. Using cap-stage-tooth germs (E14 — mouse) (Fig. 70.1), they showed that following complete dissociation of both the epithelium and mesenchymal cell derivatives, teeth could be produced when the cells were reaggregated and reassociated (Hu *et al.*, 2005a, 2005b). Thus, as observed with third-molar-tooth primordia, the cells retained their odontogenic capacity following dissociation. This property was utilized as a method of investigating the potential of non-dental cells to participate in tooth development. The experiments of Ohazama *et al.* (2004) showed that bone marrow stromal cells were able to replace all dental mesenchyme cells. Bone marrow cells were mixed with dissociated dental epithelial cells and reassociated with dental mesenchyme (Hu *et al.*, 2006). The bone marrow cells were found to contribute to ameloblast formation. In order to determine which cells within the crude marrow population might give rise to epithelial ameloblasts, cell sorting with c-kit was used to separate haematopoietic progenitor cells. When mixed with dental epithelial cells, these cells were observed to form both ameloblasts and odontoblasts. The ability of bone marrow mesenchymal progenitors (stem cells) to contribute to ameloblast formation was not assessed in these experiments. However, the principle, as originally proposed by Ohazama *et al.* (2004), that bone marrow cells can be a potential source of cells for tissue-engineering bioteeth is further supported by these reaggregation experiments. In all the experiments reported by Lesot and colleagues, the ability of nondental cells to contribute to tooth formation occurs only when the cells are mixed with dental cells from cap-stage tooth germs. The experiments reported by Ohazama *et al.* (2004) did not require a mixed population. It remains to be seen therefore whether any commercial biotooth procedure could feature the use of dissociated embryonic third-molar dental cells. Since bone marrow can be used totally to replace dental mesenchyme in the absence of any dental mesenchyme cells, the prospect exists that if a source of epithelial cells can be identified that can replace dental epithelial cells in the absence of any epithelial cells, then bioteeth could be formed totally from adult cells. Dental epithelial cells produce the signals that initiate the whole process of tooth formation, and, thus, a nondental source of these cells must in part be capable of reproducing these signals.

One signal that has been identified is BMP4, which is specifically expressed in early predental epithelium before bud formation. When exogenous BMP4 is added to nondental embryonic explants, odontoblast and ameloblast differentiation can be detected (Ohazama *et al.*, 2005). Although these cells are organized together in cell layers as they appear *in vivo*, they are not present in a recognizable tooth structure. Nevertheless, the fact that one molecule applied

to cells early can stimulate the differentiation of nondental cells into both epithelium and mesenchymal dental cells offers the possibility of engineering a dental epithelium from nondental epithelial cells.

### Root Formation

In order to be functional, bioteeth must develop roots. Root formation is a complex and little-understood process. However, although little is known of the molecules that stimulate and coordinate root formation, the absolute requirement for bone is established. If teeth form in the absence of bone, they cannot form roots, as observed in the seeded scaffold toothlike structures. When these scaffold teeth develop alongside new bone, root formation is stimulated (Young *et al.*, 2005). Tooth formation is most often studied experimentally by transplantation of tooth primordia to ectopic sites in adult rodents. The anterior chamber of the eye, the kidney capsule, the omentum, and the ear have all been used as sites that permit tooth formation. Root formation can occur at all of these sites if accompanied by bone development (Hu *et al.*, 2006). A prerequisite of any method of biotooth formation therefore is that tooth primordia be able to form teeth and roots integrated into jaw bone in the mouth. The mouth is, however, not routinely used as an experimental ectopic site for tooth development because of the difficulty of the surgery involved. In order to determine whether the adult mouth can support tooth formation, embryonic tooth primordia have been surgically transplanted into the mouths of adult mice. Not only do these develop into teeth in the mouth, but they also produce functional roots and erupt (Ohazama *et al.*, in press).

## IV. DENTAL-TISSUE REGENERATION

An important long-term goal for dental-tissue engineering is developing strategies for biotooth formation, thereby addressing many of the clinical problems arising from developmental anomalies and dental disease. However, in the shorter term there are many opportunities to be exploited for partial reconstruction of the tooth organ by tissue regeneration. Such approaches may be more readily achieved and still provide the potential for very significant impact on delivery of oral health care. Natural tissue regeneration, i.e., wound healing in the dental environment, is well recognized but represents a rather serendipitous event, and the approaches used to encourage such processes are somewhat empirical. A key factor in encouraging natural tissue regeneration is facilitating a conducive tissue environment in which the regenerative processes can take place, including moderation of chronic inflammatory events, control of bacterial infection, and minimizing tissue injury during any restorative surgical intervention. A good understanding of how to control these influences on tissue regeneration is fundamental to clinical success. There are also significant opportunities for the application of agents, whether directly through bioactive molecules or indirectly

through agents that can release tissue-sequestered pools of these molecules locally, to promote regenerative processes and tip the balance between tissue degeneration and regeneration.

### Natural Tissue Regeneration

Natural tissue regeneration implies a cellular basis to regeneration, and the nonvital nature of mature dental enamel provides major hurdles to its regeneration by any but physicochemical remineralization processes. However, the vitality of the dentin–pulp complex provides significant opportunities for regeneration. Regeneration in the dentin–pulp complex will only take place, however, if there is a conducive tissue environment. Early studies highlighted the causal link between bacteria and inflammatory events in the dental pulp, and the presence of pulpal inflammation provides an effective barrier to initiation of regeneration therein (Rutherford and Gu, 2000). Thus, if natural tissue regeneration is to be facilitated, it is essential that bacterial infection and the consequent inflammation in the tooth are controlled. Traditionally, the former has often been achieved through extensive surgical removal of infected dental hard tissues, although the trend toward minimal intervention therapy during tooth restoration potentially places the tooth at risk through incomplete bacterial control. Sealing or “entombing” the bacteria within the restoration may help to compromise their viability, as may some of the chemical agents used in the placement of dental materials. Nevertheless, control of pulpal inflammation may be desirable in the context of tissue regeneration, and an improved understanding of the inflammatory mediators involved (McLachlan *et al.*, 2004, 2005) may allow specific targeting with novel antiinflammatory molecules.

The concept of tissue regeneration in the dentin–pulp complex has been recognized since the first report of tertiary dentinogenesis in response to injury from caries by Hunter in the 18th century, and dentistry has long been a pioneer in regenerative medicine through the use of calcium hydroxide to stimulate reparative dentinogenesis to bridge pulpal exposures in the dentin (Zander, 1939). Tertiary dentinogenesis (reactionary and reparative dentinogenesis are subvariants) represents the up-regulation of the dentin-secreting cells, the odontoblasts, in teeth after completion of tooth formation to initiate tissue regeneration in response to injury. With mild injury, the odontoblasts underlying the injury survive and respond by up-regulation of their secretory activity to form reactionary dentin, while with injury of greater intensity a number of these odontoblasts undergo necrosis and may be replaced by a new generation of odontoblast-like cells secreting a reparative dentin matrix (Smith *et al.*, 1995) (Fig. 70.3).

### Importance of the Injury–Regeneration Balance

Dental caries is one of the most widespread infectious diseases globally and continues to be a major health care

**FIG. 70.3.** Schematic diagrams of reactionary (A) and reparative (B) dentinogenesis. (A) Mild carious or other injury signals up-regulation of the primary odontoblasts underlying the injury site, leading to secretion of reactionary dentin. (B) More intense injury causes necrosis of the odontoblasts underlying the injury site, and progenitor cells are recruited from the pulp to differentiate into a new generation of odontoblast-like cells, which secrete reparative dentin. Dentin bridge formation at sites of pulpal exposure arises from reparative dentinogenesis.

problem. Initially, colonization of bacteria on the tooth surface within the dental plaque biofilm leads to demineralization and proteolytic degradation of the dental hard tissues following diffusion of bacterial acids and metabolites. As the disease progresses, both the hard and soft tissues of the tooth become infected, and a sustained bacterial challenge ensues, with consequent host inflammatory responses. The dynamics of the disease process determine the opportunities for tissue regeneration through tertiary dentinogenesis — with a rapidly progressing lesion, little tertiary dentinogenesis or regeneration is seen, but in a more slowly progressing lesion, induction of tertiary dentin secretion occurs immediately beneath the lesion (Bjørndahl, 2001). Classically, this has been assumed to reflect the intensity of microbial challenge, but more recent data indicate that the response is in part due to local release of dentin matrix components. During intense carious injury, appreciable levels of dentin matrix components are released, and these compromise survival of the odontoblasts (Smith *et al.*, 2005). It is possible that growth factors contained within the dentin matrix, particularly those from the TGF- $\beta$  family, contribute to this loss of odontoblast survival, since levels of TGF- $\beta$  similar to those released from the dentin matrix have a comparable effect on odontoblast survival *in vitro* (He *et al.*, 2005). At lower doses, however, these dentin matrix components and the cocktail of growth factors contained therein can stimulate regenerative events.

It has long been recognized that particles of dentin displaced into the pulp during surgery can act as a nidus for regeneration. Implantation of solubilized dentin matrix

components in the base of either unexposed (Smith *et al.*, 1995) or exposed cavities (Smith *et al.*, 1990) induces a regenerative response of tertiary dentinogenesis. Such responses mirror those seen beneath more slowly progressing carious lesions (Bjørndahl, 2001) and suggest that the natural regeneration seen during carious and other dental-tissue injury is induced by local release of bioactive tissue matrix components. If such processes are to be successfully mimicked for development of novel regenerative therapies, it is important that we understand the nature of the signaling molecules involved.

### Signaling Events in Dental Regeneration

It seems probable that the signaling events during tertiary dentinogenesis and regeneration in the dentin–pulp complex recapitulate many of those occurring during embryonic development. During tooth development, the cells of the inner enamel epithelium of the enamel organ induce the ectomesenchymal cells at the periphery of the dental papilla to differentiate into odontoblasts through the mediation of the dental basement membrane, which may function in the immobilization and presentation of the signaling molecules (Ruch *et al.*, 1995). Growth factors, especially those of the TGF- $\beta$  family, may be key signaling molecules during induction of odontoblast differentiation (Begue-Kirn *et al.*, 1992; Thesleff and Vaahtokari, 1992). While an epithelial source of these molecules is not available in the mature tooth for signaling regeneration, sequestration of these molecules in the dentin matrix (Cassidy *et al.*, 1997; Roberts-Clark and Smith, 2000) following secretion

by the odontoblasts may provide such a source. Their release during carious demineralization (Smith *et al.*, 2005) by lactic and other bacterial acid metabolites would allow their diffusion through the dentinal tubules to the odontoblasts and pulp cells, which express receptors for these growth factors. Application of recombinant members of the TGF- $\beta$  family, either *in vitro* (Sloan *et al.*, 1999, 2000; Melin *et al.*, 2000) or *in vivo* (Rutherford *et al.*, 1994; Nakashima *et al.*, 1994; Tzaifas *et al.*, 1998), has been demonstrated to induce a regenerative response of tertiary dentinogenesis.

However, while this mirrors some of the signaling events of embryonic development, there is likely to be much reduced control over the signaling, since the rate of release of these molecular signals from the dentin matrix will be of variable intensity and the spectrum of cells with which they can interact will differ from embryogenesis.

### Control of Specificity of Dental-Tissue Regeneration

During wound healing in the dentin–pulp complex, a broad spectrum of tissue responses may be observed, ranging from regeneration of dentin tissue virtually indistinguishable from primary physiological dentin in terms of its tubularity and structure to secretion of atubular tissues with many of the structural features of bone. While terms such as *tertiary dentin*, *reparative dentin*, and *irritant dentin* have been used to encompass all of these responses, the dentinogenic specificity of some of the responses remains to be demonstrated. It is unclear, though, as to what the determinants are of the specificity of the response during natural tissue regeneration. Is it control of the molecular signaling processes, is it heterogeneity in the types of cells participating in the regeneration, or is it some other factor? Answering these questions will be fundamental to future strategies for exploiting tissue regeneration in the tooth in a controlled manner. The ability to determine whether tissue regeneration gives rise to tubular or atubular dentin matrix could be of great value in developing designer regenerative clinical approaches. For example, there may be significant benefit in directing secretion of a tubular dentin matrix in the tooth crown during regeneration to restore the normal physiological tissue architecture and function. However, it could be advantageous in possible exploitation of tissue regeneration for endodontic applications, such as root canal therapy, to generate an atubular dentin matrix, thereby providing an effective seal to the periapical region of the tooth.

### Dental Postnatal Stem Cells

The cells of the dental pulp have traditionally been considered to be neural crest–derived ectomesenchymal cells, although it is clear that during embryogenesis the migrating neural crest cells will intermingle with mesenchyme in the first branchial arch. Thus, cells of the pulp may not all share the same lineage, although those at the periphery, including the odontoblasts, appear to be of neural crest origin. In reparative situations, there are potentially a variety of

possible progenitors in the pulp for differentiation of a new generation of odontoblast-like cells, including undifferentiated mesenchymal cells in the cell-rich layer of Höhl adjacent to the odontoblasts, perivascular cells, undifferentiated mesenchymal cells, and fibroblasts. This highlights the diversity in reparative response, which may occur after injury to the tooth. While the tissues that regenerate in such situations are all referred to as tertiary dentin (reactionary or reparative variants), in reality they represent a spectrum of tissue responses, dependent on the origin of the formative cells.

During normal tooth development, it has been suggested, cells destined to differentiate into odontoblasts have to achieve a level of competence before they can respond to an inductive signal for terminal differentiation (Ruch *et al.*, 1995). If this is the case, then it may be a very restricted population of cells able specifically to give rise to odontoblasts during regeneration in the mature tooth. Just prior to terminal differentiation during tooth development, the pre-odontoblasts align perpendicular to the dental basement membrane, and after the final cell division, one daughter receives the inductive signal to differentiate into an odontoblast, while the other daughter shares a similar developmental history, with the exception of this final inductive step. It has been presumed that this latter group of cells resides in the cell-rich layer of Höhl just beneath the odontoblast layer in the mature tooth and as such, these cells would be prime candidates as progenitors for odontoblast-like cells during regeneration. Certainly, there is a decline in the numbers of cells in this subodontoblastic site with age (Murray *et al.*, 2002), which mirrors anecdotal clinical reports of impaired tissue regeneration with age. Undifferentiated mesenchymal cells are also found within the central core of the pulp, which could contribute to regenerative processes. A specific population of postnatal dental pulp stem cells (DPSCs) has also been described (Gronthos *et al.*, 2002), which show many characteristics of postnatal stem cells, although it is possible that this population of cells may be heterogeneous in its phenotype. Transplantation of these cells subcutaneously into immunocompromised mice in association with hydroxyapatite/tricalcium phosphate powder generated ectopic deposits of reparative dentin with expression of dentin sialoprotein (Batouli *et al.*, 2003).

As interest in dental regeneration increases, it is important that detailed characterization be performed of the progenitor cells involved. Primary cultures of dental pulp cells give rise to many cells with myofibroblastic characteristics, and similar results have been observed during extended serial expansion of such pulp cultures (Smith *et al.*, 2005). Whether this represents asymmetric growth of these cells or the myofibroblast phenotype represents a default phenotype is unclear, but it is probable that such cells are not true postnatal stem cells, and any attempt to label them as such should be resisted in the absence of fuller characterization. Clearly, there is potential for a spectrum of derivations for

the cells potentially involved in regeneration of the dentin–pulp complex, and the consequences of this may be a variety of phenotypic responses. It seems probable that only some of these responses may involve true postnatal stem cells. However, the diversity of cellular responses highlights the potential benefits of achieving control over these regenerative processes and the opportunities for developing strategies for directed tissue regeneration.

### Directed Tissue Regeneration

The concept of directing tissue regeneration will be successful only if it builds on the foundation of our knowledge of natural tissue regeneration, which in turn exploits our appreciation of the molecular cellular signaling events during normal tooth development. Focus on both cell- and signaling-based approaches has provided many interesting initial avenues for directed tissue regeneration in the tooth, but it is probable that the combination of these two approaches will prove the most effective in providing us with novel solutions for regenerating tooth structures.

### Signaling-Based Strategies

Signaling-based strategies have generally aimed to mimic those signaling events responsible for cell differentiation and secretion during embryonic tooth development and natural tissue regeneration. Thus, there has been a strong focus on application of growth factors, as well as various matrix-derived molecules, which also appear to stimulate regenerative events. Approaches have been used to up-regulate secretion by existing cells (reactionary dentinogenesis) as well as to induce the differentiation of new odontoblast-like cells (reparative dentinogenesis) for tissue regeneration, although the former has been constrained by our lack of understanding about the physiological control of odontoblast secretion during primary dentinogenesis.

Both *in vitro* (Sloan *et al.*, 1999, 2000; Melin *et al.*, 2000) and *in vivo* (Rutherford *et al.*, 1994; Nakashima *et al.*, 1994; Tzaifas *et al.*, 1998) application of growth factors, particularly of the TGF- $\beta$  family, to the exposed pulp in pulp-capping situations induces regeneration, although the tissue formed has shown a range of appearances, from osteodentin to tubular dentin-like. There have also been several reports of the application of matrix molecules (Decup *et al.*, 2000; Six *et al.*, 2002; Liu *et al.*, 2004), promoting dentin regeneration, and a phase II clinical trial with a synthetic peptide derived from MEPE is presently in progress. While all of these approaches provide the foundation of a new era of biologically based regenerative therapies for the teeth, there are a number of limitations. The half-life of free growth factors is generally short; for instance, that of free TGF- $\beta$ 1 is estimated to be of the order of 2–3 min. In fact, when the growth factors are sequestered within the dentin matrix, they are remarkably well protected from degradation by association with extracellular matrix components. This protective mechanism can allow the growth factors to remain

“fossilized” for the life of the tooth, thereby providing an exquisite life-long potential for natural regeneration. Also, the consequences of short half-life for these molecules and the ubiquitous presence of proteolytic enzymes in the tissue milieu at sites of injury require high concentrations to be applied for regenerative signaling. As for all tissue-regenerative and -engineering strategies, the mode of delivery of signaling molecules is key to their effective action. To date, most signaling molecules have been simply applied as lyophilized powders or aqueous solutions, but considerable potential exists for development of novel delivery systems. An alginate hydrogel has shown encouraging results for delivery of TGF- $\beta$ s for induction of *de novo* dentinogenesis on cut surfaces of pulp tissue (Dobie *et al.*, 2002), and innovative approaches are needed to deliver such molecules through the dentin matrix via the dentinal tubules. While passive diffusion through the tubules will have some effect, histomorphometry of restored human teeth suggests that natural regeneration occurs optimally when there is only a very limited residual dentin thickness, and a challenge will be to develop systems for delivery across greater distances in the dentin matrix. Gene therapy (see later) offers interesting opportunities for targeting signaling molecules to the regenerative site, although safe and suitable delivery systems are still required.

Calcium hydroxide has long been used to stimulate dentin bridge formation for dental regeneration, although its mechanism of action has remained largely elusive. Recent studies, however, have indicated that it probably acts by release of stores of endogenous bioactive molecules and growth factors sequestered within the dentin matrix, which are responsible for the cellular signaling (Graham *et al.*, 2006). The limited control on growth factor dissolution from the dentin matrix by calcium hydroxide may in part help to account for its rather variable activity during regeneration. However, its action does point to an interesting approach for regeneration where agents target release of endogenous signaling molecules from the tissue, thereby obviating some of the issues associated with the application of exogenous sources of these molecules.

### Cell- and Gene-Based Strategies

Cell- and gene-based strategies offer exciting opportunities for dentin–pulp regeneration, although many hurdles have to be overcome before these can become a clinical reality. Using electroporation, *Gdf11* gene transfer to an exposed pulp *in vivo* failed to provide effective regeneration (Nakashima *et al.*, 2002), although use of ultrasound for transfer of the *Gdf11* plasmid provided an osteodentogenic regenerative response (Nakashima *et al.*, 2003). *In vivo* gene transfer of a recombinant adenovirus containing a full-length cDNA encoding mouse bone morphogenetic protein (BMP)-7 failed to induce reparative dentinogenesis in inflamed ferret dental pulps, while *ex vivo* transduced dermal fibroblasts induced regeneration in the same model,

although the dentinogenic specificity of this response requires further characterization (Rutherford, 2001). These studies highlight the negative impact on regeneration of a nonconductive tissue environment, due to inflammation and, also, the limited numbers of stem/progenitor cells in the pulp for recruitment to participate in regeneration. The latter issue might be overcome by transplantation of suitable stem/progenitor cells for regeneration at sites of injury, especially if transduced with suitable signaling molecules. *Ex vivo* gene therapy by transplantation of *Gdf11* (Nakashima *et al.*, 2004) or *Bmp2*—electrotransfected pulp stem/progenitor cells (Iohara *et al.*, 2004)—shows promise for induction of regeneration, although the tissue formed was osteodentin-like in appearance. It is unclear whether the lack of dentinogenic specificity in these responses can be ascribed to the nature of the cells transplanted or to the inductive signaling molecules. However, the results highlight the importance of considering not only the cells and signaling molecules involved, but also the delivery mechanisms for effective therapies to be developed.

The anticipated low numbers of stem/progenitor cells for regeneration in the dental pulp indicate the need to optimize recruitment strategies for these cells, whether locally recruited from within the tissue or transplanted from without. The former approach avoids possible issues of immune reaction to nonautologous cellular material. However, local recruitment requires selection of those cells of appropriate lineage and phenotype. Cell markers for potential selection stem cells from embryonic first branchial arch tissue have been investigated (Deng *et al.*, 2004), and low-affinity NGF receptor is being targeted for selection of odontoblast-like cell progenitors from the mature dental pulp (Smith *et al.*, 2005). A combination of c-kit, CD34, and STR-1 has been reported for selection of stromal stem cells

from human deciduous dental pulps, which can be induced to differentiate into osteoblasts for bone regeneration (Laino *et al.*, 2006), while c-kit has been used for selection of odontoblast progenitor cells from bone marrow (Hu *et al.*, 2006). Use of such cell selection approaches may overcome problems associated with recruitment of stem/progenitor cells for odontoblast differentiation from a relatively small niche within the pulp during dental regeneration. Future strategies might include *ex vivo* selection of these cells for transplantation or immobilization of antibodies or other capture molecules for selection at regenerative sites for recruitment of the cells. A combination of these approaches with novel delivery of signaling molecules may prove effective in optimizing the regenerative response.

## V. CONCLUSIONS

Tissue-regenerative strategies offer exciting possibilities for development of novel clinical solutions for treatment of dental developmental anomalies and disease. The exquisite natural tissue-regenerative capacity of the dentin–pulp complex in the tooth provides an invaluable foundation on which to develop novel biologically based regenerative therapies. Particular attention will need to be focussed on both the control and the specificity of the regenerative processes, and a combination of natural and directed tissue regeneration offers many exciting opportunities for the future.

Progress in the identification, isolation, and understanding of the differentiation of embryonic and adult stem cells, together with a continuing understanding of the control of tooth development, will undoubtedly aid the production and refinement of approaches for biotooth formation. Although there remain many potential problems and pitfalls, biological tooth replacement is now a realistic possibility.

### I. INTRODUCTION

The oral and maxillofacial region is defined as the mouth and surrounding structures, bounded superiorly by the cranial base and inferiorly by the lower jaw. It is a highly complex area that includes morphologically intricate skeletal elements (Fig. 71.1), organs responsible for the special senses, lining and covering tissue (i.e., skin and subcutaneous fat), a rich neural and vascular network, and teeth. The prominent position adopted by this area makes it particularly vulnerable to injury, while the complicated interplay of events during embryogenesis of the craniofacial skeleton increases the possibility of developmental aberrations. Regular exposure to various disease-inducing agents, including complex carbohydrates (e.g., sugar), ultraviolet rays, thermal insults, and carcinogens (e.g., tobacco products), produces a variety of common pathological conditions, such as dental caries, burns, and malignant neoplasms. The loss of tissue integrity and continuity resulting from trauma, developmental deformities, and pathology imposes on physicians and dentists considerable reconstructive challenges. Meeting these requirements in the 21st century will include strategies based on tissue-engineering principles. While the discipline itself is several decades old, clinical applications for the reconstruction of the oral and maxillofacial region are currently absent. The purpose of this chapter, therefore, is to describe the special challenges posed by oral and maxillofacial reconstruction, outline

existing reconstructive techniques, and review the available literature on tissue-engineering protocols that may be relevant. Providing tissue engineers with a description of current reconstructive modalities and, in particular, their shortcomings creates a reasonable starting point on which to base the development of revolutionary, new methods. We have specifically excluded descriptions of tissue engineering of teeth and special sensory organs, because these subjects are covered elsewhere in this book.

### II. SPECIAL CHALLENGES IN ORAL AND MAXILLOFACIAL RECONSTRUCTION

Virtually all tissue types of ectodermal, mesodermal, and endodermal origin are candidates for tissue-engineering strategies and are present in the oral and maxillofacial region. However, certain structures are more commonly impacted by disease, trauma, and developmental failures and constitute the focus of our discussion, though the reconstructive methods described can be applied to rarer conditions. Common *pathological* entities include benign and malignant cystic and neoplastic processes affecting the upper (maxilla) and lower (mandible) jaws as well as degenerative conditions involving the mandibular articulation (temporomandibular joints). These diseases, or the subsequent removal of pathologically involved tissue, can produce continuity defects of the jaws requiring the replacement of

**FIG. 71.1.** The human skull is a complex region composed of many bones. Several key structures include the (A) nasal bone, (B) maxilla, (C) mandible, (D) zygomatic bone, (E) temporomandibular joint, (F) temporal bone, (G) orbital cavity, and (H) frontal bone.

bone, cartilage, and lining epithelium (Fig. 71.2). Since many of these conditions are frequently silent and the dimensions of the structures involved relatively small, their initial presentation is usually associated with significant tissue involvement. In addition to disease, nonphysiological loading of bone can produce loss of skeletal tissue, affecting the jaws and joints. *Edentulous bone loss* involves the resorption of the alveolar processes of the jaws (i.e., that portion of the jaw bone surrounding the tooth roots) following tooth removal (Fig. 71.3). This phenomenon is believed to be the result of direct loading of bone during mastication and the loss of physiological maintenance forces transmitted by the teeth. Over time, the loss of bone produces severely atrophied alveolar ridges, posing significant challenges to prosthetic reconstruction of the dentition and a predisposition to pathological fracture of the mandible (Seper *et al.*, 2004). In postmenopausal females, an increased incidence of alveolar resorption is observed following reductions in levels of bone-protective hormones (Bras *et al.*, 1983).

Degenerative diseases of the temporomandibular joints (TMJs) are commonly the result of nonphysiological mechanical forces produced by excessive ranges of motion of the joints or chronic microtrauma from various parafunctional habits (de Bont and Stegenga, 1993) (Fig. 71.4). The habits in question include jaw clenching and tooth grinding (nocturnal bruxism) and repetitive motion habits such as nail biting and gum chewing. Injury to the TMJs commonly affects the articulating surfaces of the condylar head and the glenoid fossa as well as the interpositional disc, producing a spectrum of disease from chondromalacia to severe osteoarthritis. As synovial joints, the TMJs can also fall victim to various immune-mediated disease processes, such as rheu-

(B) Coronal CT scan of the same patient with a giant cell lesion of the right maxilla that has produced marked bone destruction and displacement of developing teeth. Sinusitis of the left maxillary sinus is an incidental finding.

matoid or psoriatic arthritis (Fig. 71.5). The inflammatory component is responsible for progressive structural tissue loss leading to changes in skeletal relationships and malocclusion (Helenius *et al.*, 2005). In advanced forms of disease, replacement of both cartilage and bone as a total joint reconstruction may be necessary to restore function or skeletal support to the mandible.

Maxillofacial trauma constitutes another group of conditions providing opportunities for tissue-engineering reconstruction. Whereas most forms of blunt trauma result in fractures where tissue loss is minimal, penetrating injuries produced by high-velocity missiles and projectiles often

**FIG. 71.4.** Coronal CT scan demonstrating severe osteoarthritic degeneration of the temporomandibular joints.

create significant loss of bone and overlying soft tissue (Fig. 71.6). Finally, consideration should be given to the various forms of congenital facial clefts that commonly affect the oral and maxillofacial region. In a limited form, failure of the maxillary processes to fuse unilaterally or bilaterally produces alveolar clefts (Fig. 71.7). When the upper lip, maxilla, and palate are involved, a constellation of deformities associated with patients with unilateral or bilateral cleft lip and palate is present.

In the reconstruction of anatomical defects, the causative events must be taken into account to ensure long-term success. Defects produced by traumatic, developmental, and pathological conditions are associated with a defined endpoint. Assuming that pathology has been completely eradicated or that further traumatic insults do not occur,

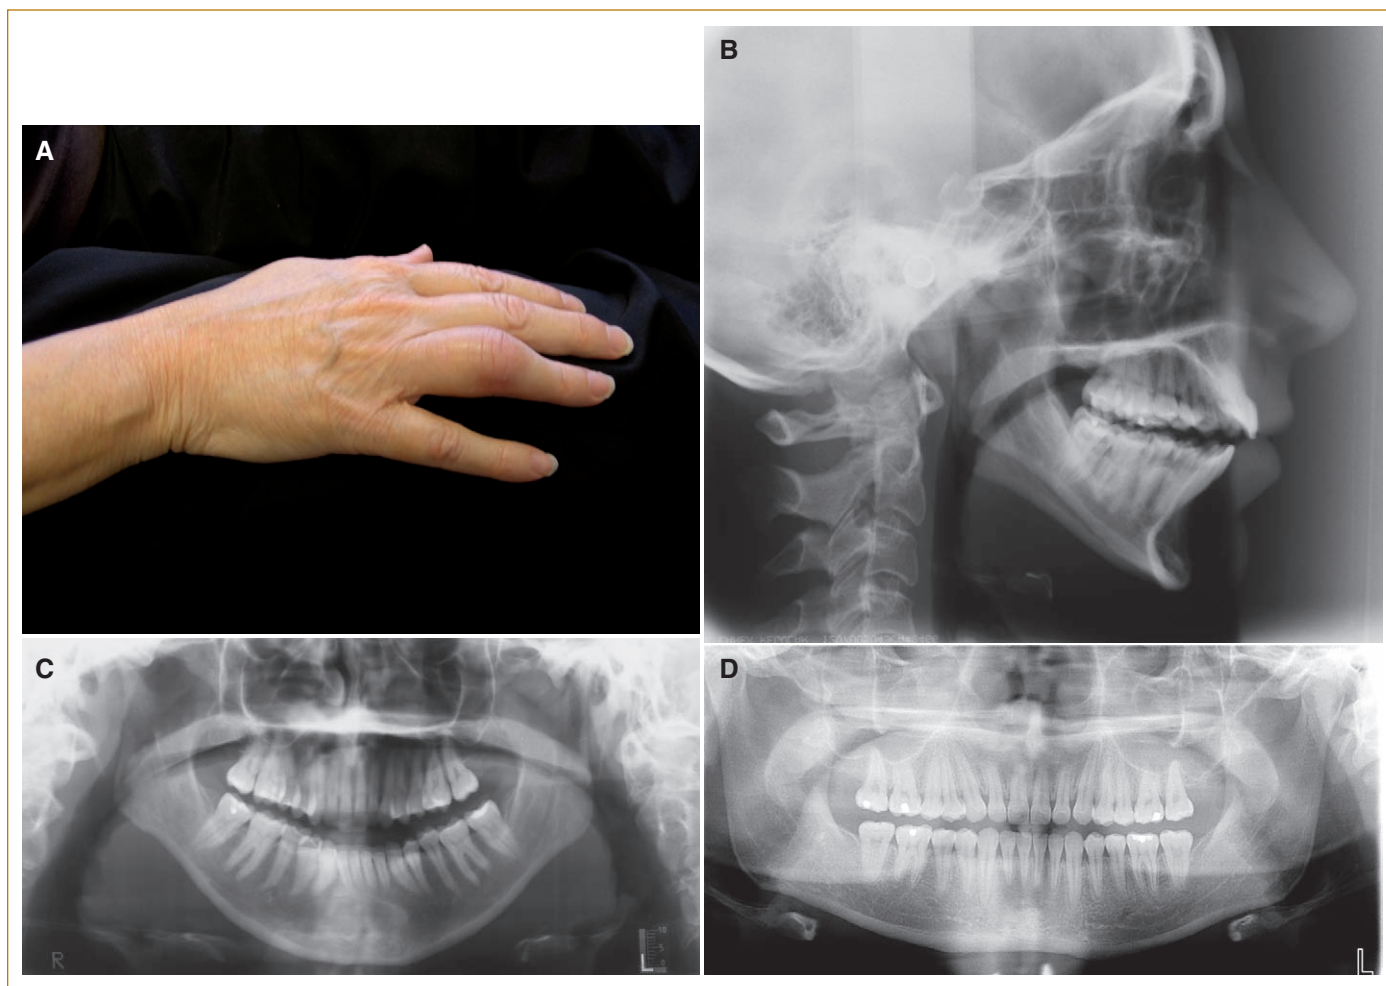

defects produced by these mechanisms can be fully characterized with respect to size and missing tissue types. In contrast, tissue loss as a result of parafunctional habits, nonphysiological loading patterns, and immunologically mediated degeneration often continue following reconstruction. This set of circumstances will adversely affect any biological constructs produced by tissue-engineering techniques and impose an important limitation on the clinical application of their use. Before biological, rather than alloplastic, materials can be employed, correction of the underlying etiology is of paramount importance.

A special concern in oral and maxillofacial reconstruction is the potential exposure of grafted tissue to the external environment. Constructs used to restore defects involving the jaws, orbits, nose, and ears are potentially in direct contact with the mouth, sinuses (maxillary, ethmoidal, and frontal), nasal passages, and external environment. These areas are characterized by high moisture content, significant bacterial populations, and functional loads imposed by physiological activities such as chewing. If biological (i.e., tissue-engineered) constructs are to survive under these conditions, modifications to account for the dilutional effects of moisture, presence of infective organisms, and mechanical loads must be provided by the engineered tissue. For example, when *in vivo* polymerization of materials is intended, the presence of fluid must be considered. Alternatively, preformed constructs can be used. Colonization of constructs with a mixed population of aerobic and anaerobic bacteria is expected with reconstructions involving oral, nasal, and sinus-related structures. Porous constructs, capable of harboring potentially pathological organisms, might be modified to reduce either bacterial attachment or replication until lining tissue develops over the implant, forming a barrier to the external environment. In addition to contaminated wound sites, tissue constructs may be exposed to complicated mechanical loads before anisotropy is restored with the regeneration of biological tissue. Both the mandible and temporomandibular joints are subject to a combination of compressive, shear, and tensile loads, depending on the type and degree of function (Christensen and McKay, 2000; van Eijden, 2000).

Another special feature of the maxillofacial region is the number of tissue types within a relatively small region. As a result of this proximity, traumatic, pathological, and developmental events often lead to the creation of composite defects requiring reconstruction of multiple tissue types. This results in a special challenge, not only to engineer composite tissues, but also to attach the various constructs to each other in their normal anatomical relationship.

Facial symmetry is an important consideration in oral and maxillofacial reconstruction. Since most structures are paired or contiguous (e.g., the orbits, zygomas, left and right maxillae, and mandible), accurate reproduction of the external form is an important aspect to preserve facial aesthetics. The paucity of overlying soft tissue as camou-

flage contributes to the exacting nature of oral and maxillofacial reconstruction, and these requirements impose on tissue-engineering methods the ability to compose and maintain accurate morphology. The advent of new, three-dimensional imaging techniques with the capacity to produce stereolithographic skeletal models that mirror both the normal anatomy and defect is a valuable adjunctive tool (Fig. 71.8). These models assist in the fabrication of scaffolds to support the reconstruction of missing tissue.

### III. CURRENT METHODS OF ORAL AND MAXILLOFACIAL RECONSTRUCTION

Several methods are used for oral and maxillofacial reconstruction, and the selection of a particular modality takes into account a number of important issues. Major factors that guide this process include the presence (or absence) of associated soft tissue, the vascularity and vas-

cular pattern present, a multidimensional characterization of the defect size, the types of missing tissue, availability of tissue for transfer, and both patient and surgeon preference. Most reconstructive techniques can be categorized into four categories:

1. Soft-tissue pedicled flaps
2. Nonvascularized soft- and hard-tissue grafts (the graft establishes, in a delayed fashion, a vascular network following implantation, relying on tissue diffusion to preserve the viability of the transplant)
3. Soft- and hard-tissue vascularized grafts (the graft is immediately perfused through an existing arterial-venous system)
4. Alloplastic reconstructions with prosthetic appliances

On occasion, composite techniques can be used, such as the staged reconstruction of a defect where soft tissue is first added to a defect site, followed by bone at a later time.

**FIG. 71.6.** Three-dimensional reconstructed radiograph of a patient with a self-inflicted gunshot wound, demonstrating the significant disruption and loss of maxillofacial skeletal structures.

### Mandibular Defects

Reconstruction of the lower jaw is indicated following removal of tissue during surgical excision of a pathological lesion or following loss of tissue from a traumatic injury. When malignant disease is present, not only is more radical removal of tissue required, but postoperative radiation therapy produces lasting compromise to both the cellularity and the vascularity of the remaining tissue. Blast effects from missile injuries can also produce significant composite injuries, with loss of bone soft tissue and diminished vascularity of the tissue bed. Two techniques are commonly employed for the reconstruction of mandibular defects. Vascularized grafts are indicated when the vascularity of the tissue bed is compromised by radiation or excessive scarring. They are also valuable when there is a requirement to replace both hard and soft tissue at the same time (Hidalgo, 1994). Hard- and soft-tissue defects can also be reconstructed using nonvascularized grafts, but their success relies on an adequately vascularized tissue bed to support the survival of transplanted cells before a new supply is established.

As composite structures, vascularized grafts either contain soft tissue alone (muscle, subcutaneous tissue with or without epithelium) or include hard- and soft-tissue components (bone and soft tissue). Since the vascular supply to bone is contained within a periosteous cuff of muscle and fibrous tissue, it is not possible to transplant only bone. The additional tissue transferred into the site of a bony defect often produces a bulky graft. While this can

**FIG. 71.7.** (A) Intraoral view of a left maxillary alveolar cleft. An oronasal fistula is present at the superiormost aspect of the cleft (see arrow). (B) Radiograph of a cleft of the maxillary alveolar bone.

be easily excised once a new vascular network is established, a second procedure performed several months after the initial transplantation is required. Another potential limitation to the use of vascularized bone grafts for the reconstruction of mandibular defects is the amount of bone available, since the dimensions of the graft are determined by the morphology of the donor site and not the size of the defect (Fig. 71.9). Special techniques, such as osteotomizing the graft and folding it on itself, have been described, but this can compromise the blood supply to the graft. Vascularized grafts are harvested from a limited number of anatomical sites characterized by a dominant arterial supply–venous drainage system. In addition, the en bloc harvesting of the graft must not compromise either the function of the donor

**FIG. 71.8.** (A) Patient following a right maxillectomy for removal of a benign odontogenic neoplasm. Defect has filled in with fibrous tissue stimulated by grafting the site with an allogeneic dermal matrix. (B) Stereolithographic model of the same patient, demonstrating the extent of the maxillary hard-tissue defect.

site or the vascular and neural supply of structures distal to the harvest. Commonly used donor sites that meet these requirements include the fibula, ilium, scapula, and distal radius. Vascularized grafts transplanted to mandibular defects are anastomosed to patent vessels adjacent to the mandible, such as the facial, lingual, or superior thyroid arteries and veins. This reconstructive approach is highly technique sensitive; and, while experienced microvascular surgeons achieve successful outcomes in over 90% of cases, less experienced surgeons or patients with underlying vascular disease (e.g., diabetes) enjoy less success.

**FIG. 71.9.** Stereolithographic model illustrating a segmental defect reconstructed with a vascularized fibula graft (single arrow). Restoration of adequate mandibular height has been achieved with the addition of a nonvascularized ilium block graft (double arrows).

Mandibular defects can also be reconstructed using nonvascularized transplantations of autologous bone from various sites. Successful bone grafts rely on adequate cellularity and a sufficiently cellular and vascular recipient bed. When the soft-tissue bed is deficient or lacks a decent blood supply, addition of well-vascularized soft tissue is achieved by the rotation of a muscle flap (with or without skin) into the mandibular defect. The pectoralis major, latissimus dorsi, and deltopectoral flaps have all been described for this purpose. The bony reconstruction is delayed for a period of three to six months until the soft-tissue flap has healed. In patients whose soft tissue is adequate but avascular as a result of radiation therapy, hyperbaric oxygen therapy can improve the quality of the vascular supply in a course of treatments lasting between four and six weeks, where repeated exposures to pressurized room air promote tissue angiogenesis. This process adds both time and considerable expense to the reconstructive process, but it has been shown to be effective in improving the quality of the recipient bed. Once the soft tissue in a mandibular defect has been optimized with respect to quantity, cellularity, and vascularity, autologous bone is transferred from a donor site and molded to fit the dimensions of the defect. The bone graft can be retained with screws fixed to a rigid bone plate or held in position with the aid of cribs fashioned from either processed allogeneic bone or alloplastic materials. Depending on the size of the defect, bone can be harvested from the anterior ilium (suitable for defects up to 4 cm in length), the posterior ilium (defects up to 8 cm in length), the tibia or mandibular symphysis and rami (defects of less than 2 cm in length). Nonvascularized grafts, especially those combined with allogeneic bone, are susceptible to infection,

particularly following exposure to the intraoral environment. When a nonvascularized graft is colonized by organisms, infection often ensues, and the graft fails to survive or integrate with the host bone. Aside from the potential for infection, nonvascularized grafts are less technique sensitive, allow complete reconstruction of a defect by customizing the volume of bone harvested, and are associated with less donor site morbidity (Marx, 1994).

### Maxillary Defects

Defects of the upper jaw pose difficult reconstructive challenges, from several perspectives, but must be undertaken to preserve speech, prevent the escape of food and fluids during eating, and maintain aesthetics. Unlike the mandible, which is related to the oral cavity alone, the maxilla is bounded both inferiorly by the mouth and superiorly by the nasal cavity and maxillary sinuses. Even when present, the thin lining epithelium does not provide a sufficiently cellular or vascular bed to support the transplantation of sufficient quantities of nonvascularized bone, and the potential for exposure of the graft to oral and nasal environments is high. Postoperative or posttraumatic scarring reduces the tissue envelope even more, further complicating reconstructive efforts. Staged reconstructions have been described involving the initial transfer of vascularized soft tissue with a pedicled flap, such as the temporalis muscle or temporoparietal flap, followed by the addition of bone several months later (Marx, 1994). As an alternative, vascularized flaps have been used because of their ability to transfer both hard and soft tissue at the same time (Bernhart *et al.*, 2003). However, the accompanying soft tissue and vascular pedicle may not be accommodated by the smaller dimensions of a maxillary defect, and this has limited their use to hemi- or total maxillary reconstructions. The simultaneous transfer of a large bulk of overlying soft tissue also results in a postoperative recovery period of several months, where the flap can prevent mouth closure and compromise eating.

As a result of these challenges, prosthetic appliances have become the most commonly used method to reconstruct maxillary defects. These devices incorporate teeth and a fitted base to separate the mouth from the superior defect (Sharma and Beumer, 2005). Excellent restoration of aesthetics as well as function can be achieved, but the fact that these devices are not permanently fixed in place and, in fact, require daily removal and cleaning reduces their acceptability by patients. In addition, adjustments are required periodically to account for remodeling of the underlying tissue bed.

The reconstruction of maxillary alveolar clefts is one exception to the use of prosthetic appliances as a primary reconstruction technique, even though they can be used very effectively to restore missing teeth in the cleft site or obturate an oral–nasal communication. When teeth are present in a cleft site, provision of bone is essential for erup-

tion and support (Eppley and Sadove, 2000). Alveolar grafting is therefore timed according to the presence and stage of development of adjacent teeth and is usually performed between the ages of 8 and 11 years. The procedure involves the development of soft-tissue flaps to isolate the mouth from the nasal cavity and placing autogenous bone between the cleft segments to restore maxillary continuity. Loss of the graft from infection, insufficient vascularity, or lack of functional stimulus is not an infrequent occurrence, and opportunities for tissue-engineering alternatives exist. This would be especially true if new interventions minimized the extent of surgery, since postsurgical scarring has been associated with restricted growth and development of the maxilla.

## IV. RELEVANT STRATEGIES IN ORAL- AND MAXILLOFACIAL-TISSUE ENGINEERING

Driven by the limited supply and inherent shortcomings of various autogenous, allogeneic, and prosthetic materials currently used for the reconstruction of oral and maxillofacial tissues, the potential for tissue-engineered biomaterials as alternatives is under serious investigation, with the hope that significantly improved therapies will result. While a diverse number of strategies are presently under development, the fundamental tenets of tissue engineering (TE) remain the same. These include consideration of the biological and mechanical properties of the scaffold material and its interactions with relevant bioactive molecules and cell populations.

Although multiple tissue types exist in the oral and maxillofacial region, TE research in this field has focused primarily on the regeneration of single tissues: the bony craniofacial skeleton, lining epithelium, the cartilages of the temporomandibular joint, auricle, and nose, and the teeth and surrounding periodontal tissue (please refer to Chapters 70 and 72 for teeth and periodontal regenerative initiatives, respectively).

### Bone Applications

An ideal biodegradable TE bone construct should combine the biocompatibility and osteoinductive potential of autologous bone with the availability and structural characteristics of allogeneic bone. Additional scaffold design considerations include porosity, pore interconnectivity, surface chemistry, and the ability to reproduce complex three-dimensional defects.

Scaffolds are responsible for a construct's initial mechanical integrity and provide surface area for cell attachment. Several biocompatible scaffold materials have been tested using *in vivo* models for craniofacial bone. Naturally derived materials (e.g., collagen, chitosan, alginate, gelatin, hyaluronic acid) (Arosarena and Collins, 2005; Hong *et al.*, 2000; Mukherjee *et al.*, 2003; Shang *et al.*, 2001; Zheng *et al.*,

2004), synthetic polymers [e.g., poly(lactic acid), poly(glycolic acid), poly(propylene fumarate), poly( $\epsilon$ -caprolactone)] (Chim and Schantz, 2006; Dean *et al.*, 2005; Meyer *et al.*, 2005; Schantz *et al.*, 2003), metals (e.g., titanium mesh) (Blum *et al.*, 2003; Sikavitsas *et al.*, 2003), and calcium phosphate ceramics (Ripamonti *et al.*, 2001) have all been tried. These materials are typically processed as porous structures or hydrogels that guide the morphology of regenerated tissue, allow for tissue ingrowth, and control the release of bioactive molecules, such as growth factors and nucleic acids. Bioactive molecules, incorporated into the scaffold from the wound itself, contribute significantly to the osteoinductive potential of the TE bone construct.

Other approaches to tissue engineering use novel biomaterials capable of implantation through minimally invasive surgery using transcutaneous photopolymerization to achieve the final scaffold form (Poshusta and Anseth, 2001). In this study, viability of osteoblasts in a photopolymerized poly(ethylene oxide) dimethacrylate scaffold was demonstrated. However, corresponding experiments employing TMJ disc cells encapsulated in alginate revealed a significant decrease in cell numbers, with no ECM production at any time point, suggesting that TMJ disc cells may not survive an encapsulated environment (Almarza and Athanasiou, 2004).

Growth factors act as mediators of cellular growth and differentiation during tissue regeneration and play an important role in extracellular matrix synthesis. Utilized as recombinant proteins in TE strategies, growth factors require a local population of target cells capable of effecting the desired response (Lieberman *et al.*, 2002). This constituency of cells may be naturally present at the wound site or added to the scaffold at the time of fabrication (Seto *et al.*, 2006) prior to implantation.

Factors that have been used for the regeneration of *in vivo* TE craniofacial bone include the bone morphogenetic proteins (BMPs) (Lutolf *et al.*, 2003; Seto *et al.*, 2006), transforming growth factor-beta (TGF- $\beta$ ) (Dean *et al.*, 2005; Hong *et al.*, 2000; Vehof *et al.*, 2002), fibroblast growth factors (FGFs) (Eppley *et al.*, 1991; Kawaguchi *et al.*, 1994), insulin-like growth factors (IGFs) (Srouji *et al.*, 2005), and platelet-derived growth factor (PDGF) (Vikjaer *et al.*, 1997). The bulk of experience concerning the use of growth factors for bone repair has involved BMPs (Nussenbaum *et al.*, 2004), and this popularity has been extended into clinical investigations using recombinant human BMP-2 (rhBMP-2) for alveolar ridge augmentation (Cochran *et al.*, 2000; Fiorellini *et al.*, 2005; Jung *et al.*, 2003), maxillary sinus floor augmentation (Boyne *et al.*, 2005), mandibular reconstruction following tumor resection (Moghadam *et al.*, 2001), and distraction-assisted alveolar cleft repair (Carstens *et al.*, 2005; Chin *et al.*, 2005).

Jung *et al.* (2003) examined the effect of combining recombinant human BMP-2 with a xenogeneic bone substi-

tute in order to improve membrane-guided bone regeneration therapy of osseous defects in areas of dental implant placement. Although there was no statistically significant difference in percentage of newly formed bone at the rhBMP-2-treated site versus the control site at six months, a larger fraction of mature lamellar bone (76% vs. 56%) as well as increased graft to bone contact (57% vs. 29.5%) were present in the experimental sites.

In addition, Boyne *et al.* (2005) completed a phase II randomized controlled study investigating the safety and efficacy of rhBMP-2 combined with an absorbable collagen sponge (ACS) versus bone graft for staged maxillary sinus floor augmentation. It was concluded that rhBMP-2 had a similar safety profile to bone graft, with the added benefit of lacking donor site morbidity. In addition, the rhBMP-2/ACS treatment induced similar amounts of bone to the bone graft group, allowing for the placement and long-term functional loading of dental implants in approximately 75–80% of the patients treated.

The clinical use of rhBMP-2 to regenerate much larger bone defects has also been reported in the literature. Carstens *et al.* (2005) described the use of “distraction-assisted *in situ* osteogenesis” (DISO) to treat a severe facial cleft, in which rhBMP-2/ACS implantation was combined with distraction osteogenesis to create the patient’s ramus and condyle as part of the surgical reconstruction.

A similarly spectacular application of rhBMP-7 has been described by Warnke *et al.* (2004) for the reconstruction of a 7-cm mandibular continuity defect in a patient who had received ablative tumor surgery and subsequent radiation treatment. A bone-muscle-flap prefabrication technique was utilized, in which computed tomography and computer-aided design techniques were used to fabricate a custom titanium mesh cage replicating the contours of the missing mandible. Within this cage, a combination of xenogeneic bone mineral blocks coated with rhBMP-7 and autologous bone marrow was placed, prior to implantation of the entire construct within the latissimus dorsi muscle of the patient. Following seven weeks of implantation within this “*in vivo* bioreactor,” the viable mandibular replacement was harvested from the patient, along with part of the muscle containing a major artery and vein, which were subsequently anastomosed with vessels at the recipient site using microsurgical techniques. Four weeks after this transplantation surgery, the patient was able to undertake a small amount of mastication and enjoy more solid foods.

A significant drawback to growth factor strategies in tissue engineering is the shortage of naturally derived factors isolated from biological tissue. This deficiency has been addressed with the development of techniques to produce biologically active proteins using recombinant-engineering techniques. However, the use of recombinant proteins is not without concern (Nussenbaum *et al.*, 2004). Compared to animal models, bone regeneration in humans does not

appear to be as robust. In order to overcome this species recalcitrance, administration of factors in excess of naturally occurring concentrations appears to be necessary. The augmented administration of exogenous factors may potentially stimulate harmful biological effects, such as malignant transformation of cells, and also prove to be too expensive when compared to alternative techniques for tissue regeneration.

Attempts to address the shortcomings of recombinant protein-based strategies have spurred investigation into the use of gene delivery for tissue engineering. By delivering the gene for the expression of a protein with specific effects on a target cell population, successfully transfected cells will elaborate the protein constitutively. This results in higher and more constant levels of protein production (Hannallah *et al.*, 2003). However, while both viral (Alden *et al.*, 2000; Dunn *et al.*, 2005; Lindsey, 2001) and nonviral (Huang *et al.*, 2005) gene delivery vectors have been utilized for bone regeneration in cranial-defect animal models, compromises must be made with each. Adenoviral constructs have commonly been used as viral vectors to transfect craniofacial tissues and have the advantage of efficiently transfecting both replicating and quiescent cells (Warren *et al.*, 2003). In addition, adenoviruses are easily manipulated and can be produced in high titers, and large amounts of genetic information can be inserted into them. However, concerns related to viral vectors include *in vivo* homologous recombination and the possibility of an immune response from the expression of viral antigens on the surfaces of transfected cells. These concerns have led to the development of nonviral vector agents (Hannallah *et al.*, 2003).

While numerous nonviral gene delivery systems exist, a common problem is their low *in vivo* transfer efficiency (Warren *et al.*, 2003). Nonetheless, such systems are able to deliver much larger genes with minimal immunogenicity. One promising modality of nonviral gene delivery for craniofacial applications is the use of cationic liposomes, which have been used to regenerate cranial-bone defects in rabbits by delivering BMP-2 plasmid cDNA (Ono *et al.*, 2004). The low transfection efficiency of uncondensed, naked plasmid DNA has also been addressed by the use of the cationic macromer poly(ethylene imine), which has been used to condense BMP-4 plasmid DNA and deliver it in a sustained and localized manner from poly(lactic-co-glycolic acid) scaffolds within critical-size cranial defects (Huang *et al.*, 2005).

Gene transfection can take place directly within the defect site by releasing the delivery vector *in vivo* from the TE scaffold (Alden *et al.*, 2000; Dunn *et al.*, 2005). Indirect delivery methods have also been described utilizing a target cell population harvested from the patient, performing *in vitro* transfection of the cells, and then reimplanting the transfected cells into the defect along with the TE scaffold material (Blum *et al.*, 2003; Edwards *et al.*, 2005; Nussenbaum *et al.*, 2003). While the direct technique may

be simpler, it has a lower transfection efficiency and targets cells in a nonspecific manner (Nussenbaum *et al.*, 2004). The indirect *ex vivo* approach, on the other hand, requires additional harvesting and culturing procedures but avoids the risks associated with placing viral vectors directly into the patient and disturbing the host genome. *Ex vivo* transfected cells are not immunologically privileged and may still express viral antigens on their surface, which can lead to a host response following implantation.

Alternative TE approaches to craniofacial reconstruction employ cell-seeded scaffolds as implants. These have potential benefits for regenerating tissues with compromised healing capacity, such as those affected by radiation therapy (Nussenbaum *et al.*, 2003). Adult-derived mesenchymal stem cells (MSCs) retain the ability to form several of the tissues present in the craniofacial region, including bone, cartilage, muscle, tendon, and adipose tissue, making them ideal candidates for the seeding of bone TE constructs (Caplan and Bruder, 2001). However, the relative scarcity of MSCs derived from adult bone marrow (1 per 100,000 cells in adults, 1 per 2 million cells in the elderly) requires significant expansion of cell numbers *in vitro* before their use in cell-seeded TE scaffolds (Fong *et al.*, 2003). Autologous, culture-expanded MSCs have been utilized in combination with alginate hydrogels for the treatment of large cranial-bone defects in sheep (Shang *et al.*, 2001). Production of osteoblasts has been promoted by culturing MSCs in flow-perfusion bioreactors. This technique uses the inherent osteoinductive potential to elaborate bonelike extracellular matrix and fluid shear stresses synergistically to enhance the differentiation of MSCs toward an osteoblastic phenotype (Datta *et al.*, 2006). These *in vitro* fabricated cellular/ECM constructs have tremendous potential in bone TE applications.

Aside from the biological components of tissue-engineering constructs, scaffold properties are also extremely important to the overall success of any particular strategy. A common misconception is that bone TE scaffolds for craniofacial applications do not require substantial strength, since the craniofacial skeleton is not subjected to heavy loading. However, *in vivo* studies demonstrate that many craniofacial bones undergo levels of strain similar to that experienced by the appendicular skeleton (Herring and Ochareon, 2005), substantiating the need for mechanical strength of potential bone TE scaffolds. Ideal scaffold design must therefore reconcile the need for high porosity and interconnectivity, which promotes tissue ingrowth and scaffold degradability, with a requirement for mechanical strength. While computational methods for designing and fabricating scaffold architectures to optimize both pore interconnectivity and load-bearing characteristics have been performed (Hollister *et al.*, 2005), the final constructs must still be tested in animal models to determine their suitability in clinical applications.

The surface characteristics of bone-tissue-engineering scaffolds also determine their ability to regenerate tissue in the wound-healing environment. Surface chemistry has a significant effect on the interactions between the cell populations present in the defect and the biomaterial. Hydrophilic synthetic polymers such as oligo[poly(ethylene glycol) fumarate] (OPF) have been shown to impede bone healing in extraction sockets as compared to the hydrophobic polymer poly(propylene fumarate), based on the OPF macromer's prevention of protein adsorption and hence cell adhesion (Fisher *et al.*, 2004). Interestingly, the resistance of OPF hydrogels to generalized cell adhesion has been used to advantage in the fabrication of biomimetic scaffolds, which are able to selectively encourage the migration of osteoblasts *in vitro* through the addition of specific binding peptides to their surfaces, such as osteopontin-derived peptide (Shin *et al.*, 2004).

### Cartilage Applications

Compared to bone, far less work has been conducted into tissue engineering cartilage within the craniofacial region. This can be attributed partly to the disparate roles cartilage plays in different sites. For example, a tissue-engineered TMJ disc must be able to move in association with the joint while improving congruity between the articulating surfaces, while the cartilages of the auricle and nose provide skeletal support to the overlying soft tissue.

While *in vitro* expansion and seeding of harvested chondrocytes into degradable polymer scaffolds is capable of producing cartilage following implantation in immunocompetent-animal models (Chang *et al.*, 2003; Kamil *et al.*, 2004; Shieh *et al.*, 2004), the clinical experience has been somewhat disappointing with resorption of tissue-engineered auricular cartilage after several months (Rotter *et al.*, 2005). To date, engineered implants have yet to achieve the aesthetic appearance and stability of silicone-based maxillofacial prosthetic devices (Nussenbaum *et al.*, 2004). In contrast to efforts with nasal and auricular reconstruction, tissue-engineered cartilage constructs have enjoyed greater success in orthopedic applications when used to regenerate osteochondral defects within the articulating surfaces. This difference is believed to be the result of the relatively immunoprivileged properties of the synovial joint environment.

Replacement of fibrocartilage to restore the articulating surfaces or interpositional disc of the TMJs constitutes a special challenge, including identifying a suitable source of healthy fibrochondrocytes. To date, the most commonly used cells have been derived either from the disc itself (Almarza and Athanasiou, 2004, 2005, 2006a, 2006b; Bean *et al.*, 2005; Detamore and Athanasiou 2004, 2005b; Springer *et al.*, 2001; Thomas *et al.*, 1991) or from articular cartilage (Girdler, 1998; Puelacher *et al.*, 1994; Springer *et al.*, 2001). In order to create a sufficient number of cells to populate a construct, multiple passages are required. Unfortunately,

chondrocytes have been found to dedifferentiate into a more fibroblastic phenotype after only a couple of passages (Darling and Athanasiou, 2005), and cells from later passages also exhibit decreased extracellular matrix (ECM) protein expression (Allen *et al.*, 2006a). Consequently, before TMJ disc engineering becomes a viable technique, a cell source that can yield a large population of TMJ disc cells, or a population of cells that rapidly fills a scaffold, must first be identified.

The earliest tissue-engineering study directed at reconstruction of the TMJ disc utilized a porous collagen scaffold seeded with articular cartilage cells. After two weeks, the construct appeared similar to a disc with regard to gross morphology and cell shape (Thomas *et al.*, 1991). Later efforts tested fibers of poly(glycolic acid) (PGA) and poly(lactic acid) (PLA) and concluded that both materials were able to support cell attachment and matrix production and exhibited acceptable mechanical properties after 12 weeks (Puelacher *et al.*, 1994). Another study, comparing PGA, polyamide filaments, expanded polytetrafluoroethylene (ePTFE) filaments, and bone blocks (Springer *et al.*, 2001), demonstrated cell attachment and limited collagen production, but neochondrogenesis was not observed after four and eight weeks. While PGA is an acceptable scaffold substrate, the material degrades exceedingly rapidly, leaving constructs with limited mechanical integrity after only a few weeks. As an alternative, PLA nonwoven mesh has been tried, and initial results show promise, with retention of tensile and compressive integrity over a similar time scale (Allen and Athanasiou, 2006b; Almarza and Athanasiou, 2005).

*In vivo* investigations of implanted tissue-engineered TMJ discs are limited (Puelacher *et al.*, 1994), although extensive mechanical, histological, and biochemical testing has been conducted as a preliminary step to characterize the behavior of the natural disc and constructs fabricated *in vitro* (Almarza and Athanasiou, 2004, 2005; Detamore and Athanasiou, 2003, 2005a, 2005b). For instance, the disc has been shown under conditions of unconfined compression to exhibit regional variations with regard to stiffness (Allen and Athanasiou, 2006c). The medial and anterior regions of the disc are more stiff than with other sites. Variations are also present between the superior and inferior surfaces of the disc, with the inferomedial and superoanterior regions demonstrating greater stiffness. Appreciating the regional characteristics of the disc becomes important as dynamic loading patterns of the joint during function are considered. Attempts at correlating this behavior to the distribution of glycosaminoglycans throughout the disc have not been uniformly successful, and other factors, such as collagen fiber size and orientation, may play a greater role in affecting the material properties.

Several studies have demonstrated the potential of growth factors for TMJ cartilage-tissue engineering. This potential was first observed in an experiment comparing the effects of transforming growth factor- $\beta_1$  (TGF- $\beta_1$ ) with

prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) on bovine TMJ disc cells in monolayer. TGF- $\beta$ <sub>1</sub> increased cell proliferation 2.5-fold, while PGE<sub>2</sub> had no significant effect (Landesberg *et al.*, 1996). The effects of platelet-derived growth factor (PDGF), insulin-like growth factor (IGF), and basic fibroblast growth factor (bFGF) have also been assayed, using monolayer cultures of porcine TMJ disc cells. The results of these studies suggest that lower concentrations favor biosynthesis while higher concentrations favor proliferation (Detamore and Athanasiou, 2004). The most beneficial growth factors appear to be IGF-I and bFGF, both of which produce significant increases in collagen synthesis and cell proliferation. Since native tissue is exposed to a variety of growth factors, combination strategies are likely to prove more beneficial than single-factor therapy. To explore this hypothesis, IGF-I and bFGF in low concentration were combined with bFGF and TGF- $\beta$ <sub>1</sub>. This cocktail successfully demonstrated increased collagen production when applied to porcine TMJ disc cells seeded on PGA scaffolds (Detamore and Athanasiou, 2005a). However, while constructs exposed to growth factor combinations improved structural integrity and overall cellularity, a statistically significant improvement in biochemical or mechanical properties was not demonstrated (Almarza and Athanasiou, 2006b).

Although growth factors have received the most attention, positive biochemical stimulation is also likely to come from culture conditions and cellular interactions. An ascorbic acid concentration of 25  $\mu$ g/mL has been shown to produce constructs with higher total collagen content and higher aggregate modulus relative to concentrations of 0  $\mu$ g/mL or 50  $\mu$ g/mL (Bean *et al.*, 2005). This was likely associated with improved seeding observed for the constructs cultured in 25  $\mu$ g/mL of ascorbic acid. Initial cell seeding is another important consideration in any tissue-engineering construct, due to cell-to-cell interactions and signaling. It has been shown that PGA scaffolds seeded at saturation increased cellularity and ECM content relative to scaffolds seeded below saturation (Almarza and Athanasiou, 2005).

The native TMJ disc undergoes significant compression, tension, and shear (Tanaka *et al.*, 2003). While cells proliferate and produce ECM in static culture, mechanical stimuli may be required to produce an optimal tissue-engineered construct. A variety of mechanical stimuli may be beneficial, including compression, tension, hydrostatic pressure, and fluid shear stress. An extensive review of the mechanical bioreactors that have been used in engineering cartilaginous tissues has been published on the subject (Darling and Athanasiou, 2003).

Three recent studies have investigated the effects of mechanical stimulation on TMJ disc constructs. A low-shear fluid environment by means of a rotating wall bioreactor created constructs with dense matrix and cell composition (Detamore and Athanasiou, 2005b); however, when the biochemical content of these constructs was compared to

that of those grown in static culture, no clear benefit of the bioreactor was observed. When disc cells were exposed to hydrostatic pressure in monolayer or PGA scaffolds, constant hydrostatic pressure at 10 MPa increased collagen production as compared to static culture (Almarza and Athanasiou, 2006a). In contrast, intermittent hydrostatic pressure from 0 to 10 MPa at 1-Hz frequency was detrimental to the constructs, producing less collagen and GAGs than unloaded controls. These results were consistent in both two- and three-dimensional cultures. In another recent study, dynamic tensile strain significantly reduced interleukin-1 $\beta$ -induced up-regulation of matrix metalloproteinase (Deschner *et al.*, 2006). This may have implications on future tissue-engineering studies, since MMPs play an important role in ECM degradation and remodeling.

### Composite-Tissue Applications

Success with the regeneration of single tissue types, such as bone and cartilage, has encouraged investigators to attempt the reconstruction of structures composed of multiple tissue types. Such anatomic structures may exist as composites of hard and soft tissues, which differ in their cellular composition and mechanical properties yet perform as a single functional unit (Rahaman and Mao, 2005).

The temporomandibular joint condyle serves as an example of a maxillofacial composite structure consisting of articular cartilage and subchondral bone and provides an excellent opportunity for composite osteochondral-tissue engineering. A study performed by Alhadlaq *et al.* (2004), used adult bone marrow MSCs, expanded in culture and induced to differentiate into separate osteogenic and chondrogenic lineages *in vitro*. The resultant cells were then encapsulated in poly(ethylene glycol)-based hydrogels and the cell-polymer solutions cross-linked in a mold that provided the correct stratified organization of the osteogenic and chondrogenic layers. Finally, the osteochondral constructs were implanted into the dorsum of immunodeficient mice for up to eight weeks. Histological and immunohistological analyses revealed both structural and immunohistochemical differences between the osteogenic and chondrogenic layers, which served as a primitive proof of concept of the potential for composite-tissue-engineered constructs in the craniofacial region.

### Animal Models

As tissue-engineering strategies become more sophisticated, the complex interactions between multiple cell populations, growth factors, and scaffold biomaterials require testing within clinically relevant *in vivo* healing environments. While computational models and *in vitro* testing provide proof-of-concept verification of a particular tissue-engineering strategy, more challenging test beds utilizing animal models are ultimately required, to allow discrimination of the healing potential of different biomaterial constructs (Guldberg *et al.*, 2004).

**FIG. 71.10.** Intraoperative photo of the rabbit mandibular critical-size bone defect. Reprinted from Young *et al.* (2007) with permission from Wiley & Sons, Inc. Copyright 2007.

The ideal model for testing the validity of tissue-engineered bone constructs is the *critical size defect* (CSD): namely, an intraosseous defect that will not heal by bone formation during the lifetime of the animal (Hollinger and Kleinschmidt, 1990). Several CSD models have been described in the literature, including the cranial cavitation defect (Blum *et al.*, 2003; Dean *et al.*, 2005) and long-bone segmental defect (Hedberg *et al.*, 2005a, 2005b). These models do not accurately describe the oral and maxillofacial environment, because they do not simulate the unique masticatory stresses and cell populations seen in mandibular or maxillary wound healing. Mandibular defects have been described in rats, but they have the disadvantages of poor surgical access and a tendency for implanted materials to fall into the fascial spaces (Hollinger and Kleinschmidt, 1990). Conversely, larger animals, such as dogs (Huh *et al.*, 2005), minipigs (Henkel *et al.*, 2005), goats (Fennis *et al.*, 2005), and nonhuman primates (Fritz *et al.*, 2000), offer the advantages of easy surgical access and the ability to create large defects, but they are expensive to maintain.

To address the lack of an easily accessible, readily reproducible CSD model in an animal that was inexpensive and easy to maintain, a 10-mm, cylindrical, bicortical mandibular defect model in the New Zealand white rabbit was created (Young *et al.*, 2007) (Fig. 71.10). Both quantitative and qualitative outcome measures using histology (Fig. 71.11) and micro-computed tomography (Figs. 71.12 and 71.13) were used to evaluate the bone healing within this novel mandibular-defect model, which was shown to lack bone bridging at four months. It has also been shown that vascular ingrowth can be quantified in this model, making it an ideal testbed for angiogenic-tissue-engineering strategies as well.

**FIG. 71.11.** Coronal section (stained with H&E) showing representative 16-week tissue repair within the rabbit mandibular critical-size defect. Scale bar represents 5 mm. As shown, the full-thickness defect at 16 weeks displays a lack of bony bridging across the center (arrow). Note that the image is oriented with the buccal surface on the left.

**FIG. 71.12.** Micro-CT-generated coronal tomogram showing representative 16-week defect healing of the critical-size defect. Qualitative micro-CT findings in terms of bone formation at 16 weeks were similar to the histological findings seen in Fig. 71.11.

**FIG. 71.13.** Micro-CT-generated representative three-dimensional reconstructions. Note the buccal aspect of the specimen is shown on the top, with the lingual aspect on the bottom. The critical-size defect at 16 weeks shows a through-and-through defect and a lack of bony bridging across its center. Reprinted from Young *et al.* (2007) with permission from Wiley & Sons, Inc. ## V. FUTURE OF ORAL- AND MAXILLOFACIAL-TISSUE ENGINEERING

While significant progress has been made toward our ability to fabricate tissue in the laboratory for the reconstruction of defects in the oral and maxillofacial skeleton, considerable challenges remain before these techniques are embraced as a feasible clinical modality. Some of the issues pertain to tissue engineering itself, such as the ability to identify and harvest a suitable population of cells capable of fulfilling the functions of the desired tissue, supporting cellular differentiation and reproduction through physiological levels of growth and attachment factors, promotion of vasculogenesis, and the development of matrices that fulfill the physical requirements of a skeletal site. Since many of the structures in the oral and maxillofacial region are composed of multiple tissue types, the ability to engineer composite structures is also important, as is consideration of the unique environment to which tissue-engineered constructs are exposed. Even as these demands are met, other factors must be considered before TE tissue can be adopted as part of a reconstructive surgeon's armamentarium. Existing reconstructive techniques were originally based on macroscopic concerns for restoring the shape and size of a missing structure. Since TE is essentially based on cells, a microscopic appreciation of the function of a particular tissue type must first be derived. At this time, characterization of the function and pathological degradation of many of the structures in the oral and maxillofacial region is unfortunately deficient. In other words, before the replacement for a structure can be appropriately engineered, a better understanding of the function and local environment must first be achieved. This is particularly true of defects produced by ongoing pathological processes, where correction of the condition must precede replacement with yet another biological substrate. The future of oral and maxillofacial TE therefore lies in the hands of close collaborations between engineers and clinicians together.

### I. INTRODUCTION

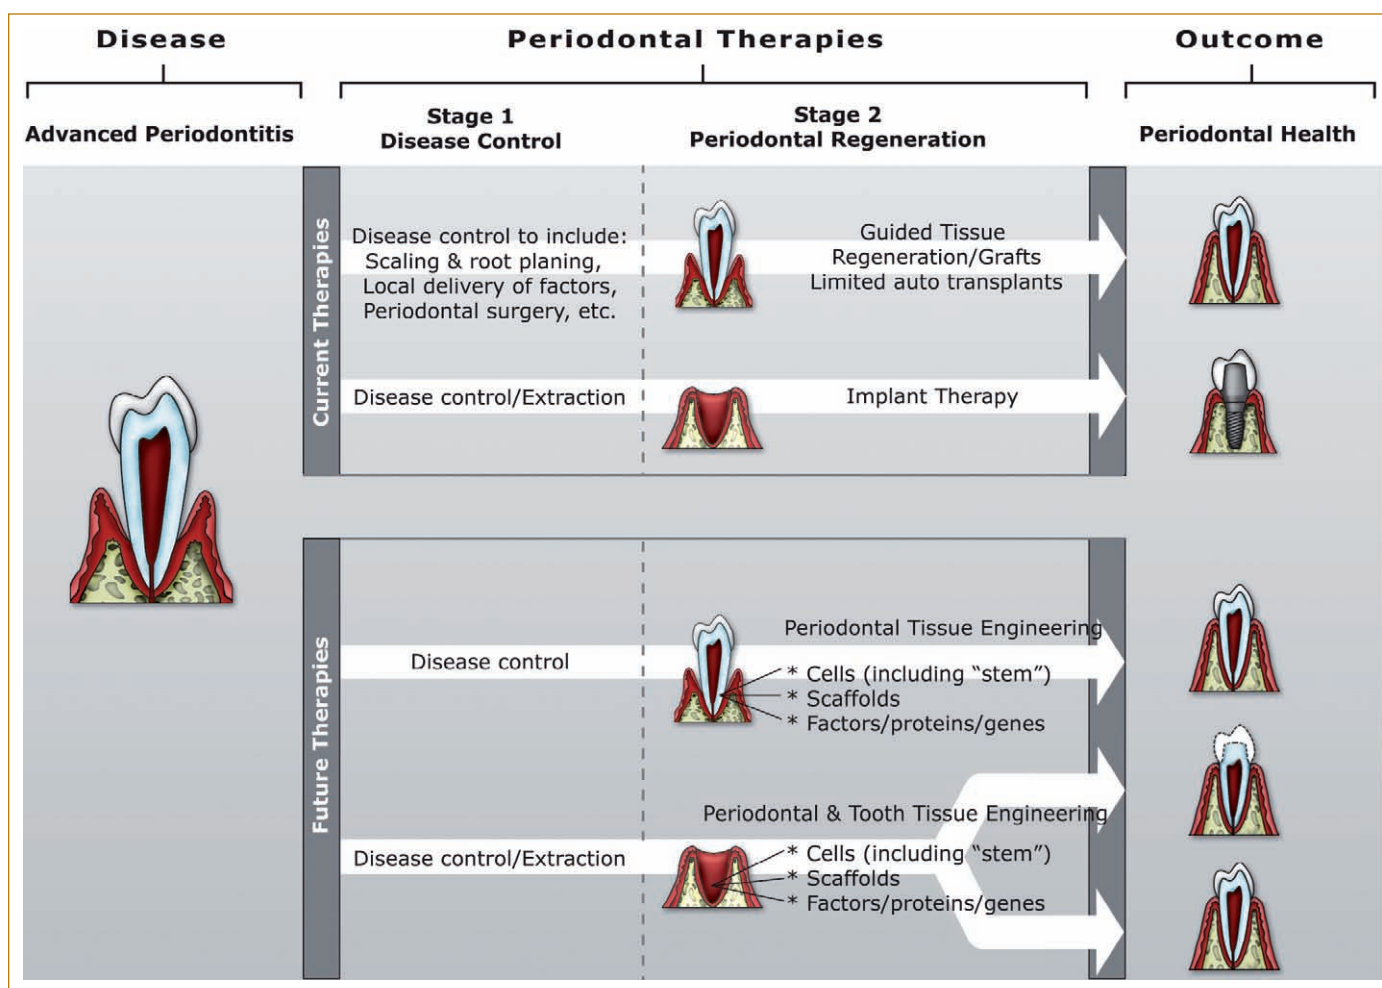

Existing data from the National Institute of Dental and Craniofacial Research, National Institutes of Health, indicate that 86% of adults over the age of 70 have at least moderate periodontal disease, with approximately 25% having lost their teeth (Albandar *et al.*, 1999). Oral infections may have a marked negative impact on health and quality of life. Interestingly, but not surprisingly, millions of dental-oral-craniofacial procedures, ranging from tooth restoration to reconstruction of facial hard and soft tissues, are performed annually, compared with roughly 20,000 organ transplants and 500,000 joint replacements. The recognition that periodontal tissues, i.e., bone, cementum, and periodontal ligament, possess the capacity to repair/regenerate has led to substantial efforts focused on understanding the biologic basis for this activity and applying the knowledge gained to designing therapies that predictably promote periodontal tissue regeneration. This chapter covers some of the approaches that have been used.

In this first section a basic review of current therapies used to treat periodontal diseases is presented and a figure depicting current treatment modalities for damaged periodontal tissues and future approaches for regenerating lost periodontal tissues is provided (Fig. 72.1). The next section gives an overview of factors, known to and/or with strong evidence that they affect the behavior of cells associated with the regeneration of periodontal tissues. The following section discusses current approaches and future directions

being investigated for regenerating periodontal tissues, with a focus on cells considered to play a role in the formation of periodontal tissues, both during development and regeneration, and on delivery of factors and cells to local sites. The final section offers future directions/areas in need of research in order to design predictable regenerative treatment modalities for our patients.

The periodontium consists of the tissues supporting and investing the tooth and include the gingiva, periodontal ligament, cementum, and alveolar bone. Periodontal diseases are chronic inflammatory diseases caused by bacteria but also linked to trauma, environmental insults, genetic disorders, and systemic diseases. Periodontal diseases are manifested in the loss of both hard and soft tissues of the periodontium and eventual tooth loss if left untreated.

Researchers and clinicians in the field of dental-oral-craniofacial biology are among the leaders in applying bioengineering principles to regenerate tissues/organs. Dental materials have been and continue to be a major and successful area of focus, with advances in materials used to restore tooth structure (crown) in terms of adherence, aesthetics, and endurance; and in impression materials for assisting in the fabrication of crowns, dentures, partials, and other oral-craniofacial parts (Bayne, 2005). Knowledge gained from research targeted at improving the treatment modalities for replacing lost dental-oral-craniofacial tissues has resulted in enhanced bridge design for aesthetics and superior tissue integrity and tooth support, in more aes-

**FIG. 72.1.** Role of tissue engineering in periodontal therapies: Current status and future directions.

thetic replacement materials, and in an improved/increased variety of implants to select from for use as single and multiple tooth abutments.

Alternative approaches for the replacement of a single tooth include autotransplantation; but beyond the limitation that an individual must have a tooth/teeth for transplantation (e.g., third molars), reports of success have been limited (Gault and Warocquier-Clerout, 2002; Kallu *et al.*, 2005). In addition, several advances have been made in the application of graft materials and barrier membranes, often coupled with grafts, polymers, factors, and local delivery of factors. For example, antimicrobial agents are available for local delivery to periodontal pockets as a means of decreasing microbes locally without having to use a systemic approach for drug delivery. Further, oral-dose doxycycline (a tetracycline) is marketed as metalloproteinase inhibitor, but without antimicrobial activity. Low-dose doxycycline inhibits collagenase activity via decreasing availability of calcium, a requirement for activating collagenase, thereby decreasing collagen degradation normally associated with

the inflammatory response to bacteria. Unfortunately, while there have been some positive results with all of these approaches, the results are often not optimal and also not predictable (Wang *et al.*, 2005).

Fortunately, research approaches have provided insights into agents with potential for use in regenerating several tissues, including periodontal tissues. Areas of research focus that have had positive outcomes in the field of periodontal bioengineering include (a) defining the regulators controlling development of the periodontium; (b) understanding how healthy tissues are maintained with age; (c) recognizing the mechanisms that allow certain tissues, e.g., bone, to regenerate post trauma/disease; (d) unraveling the complexities of wound healing; (e) establishing stem cell properties within periodontal tissue biology; and (f) establishing the requirements for designing scaffolds/delivery systems for use in treating lost periodontal tissues. With the growing body of knowledge as to the cellular and molecular events controlling development and regeneration of tooth structures, the potential for designing predictable

**Table 72.1.** Effects of putative periodontal regenerative factors on periodontal tissues

<i>Growth factor</i>	<i>Effects: known and/or suggested</i>
Platelet-derived growth factor (PDGF)	Promotes migration, proliferation, and noncollagenous matrix synthesis of mesenchymal cells
Insulin-like growth factor-1 (IGF-1)	Promotes cell migration, proliferation, differentiation, and matrix synthesis of mesenchymal cells
Fibroblast growth factor-2 (FGF-2)	Promotes proliferation and attachment of endothelial cells and PDL cells and wound healing
Transforming growth factor-beta (TGF- $\beta$ )	Promotes proliferation of cementoblasts and PDL fibroblasts
Selected bone morphogenetic proteins (BMPs)	Promotes proliferation, differentiation of mesenchymal cells, e.g., PDL fibroblasts, follicle cells, fibroblasts, toward a cell with capacity to form mineral matrix, e.g., osteoblasts, cementoblasts
Selected products of ameloblasts/epithelial cells, e.g., Emdogain (EMD); amelogenins (LRAP/TRAP); ameloblastin	Suggested roles in enhancing proliferation, protein synthesis, cell maturation, and mineral nodule formation in follicle cells, PDL cells, odontoblasts, osteoblasts, and cementoblasts and in wound healing
Selected anabolic factors, e.g., parathyroid hormone (PTH)	Intermittent PTH has been shown to promote bone formation <i>in vitro</i> and <i>in vivo</i>
Phosphates	Existing data suggest that cells within the periodontium are highly sensitive to changes in phosphate/pyrophosphate levels and further that phosphates, beyond being a physical-chemical regulator of crystal growth, may directly control expression of genes associated with maturation of cementoblasts and osteoblasts

bioengineering approaches to replace/regenerate lost periodontal tissues is great. The next section is devoted to discussing some of the factors that hold promise for use in reconstructing periodontal tissues.

## II. FACTORS FOR PERIODONTAL TISSUE ENGINEERING AND REGENERATIVE MEDICINE

Following periodontal injury, a fibrin clot is formed at the wound site, releasing tissue growth factors locally, such as platelet-derived growth factor (PDGF) and transforming growth factor-beta (TGF-beta), from degranulating platelets (Okuda *et al.*, 2003; Tozum and Demiralp, 2003). These mitogenic polypeptides attract mesenchymal cells and fibroblasts to migrate into the periodontal wound and stimulate their repopulation in the defect (Marcopoulou *et al.*, 2003). The continuing process of periodontal tissue repair is followed by the formation of granulation tissue as a source for future periodontal connective tissue cells, such as osteoblasts, periodontal ligament fibroblasts, and cementoblasts (Bosshardt, 2005). One requirement for success in regenerating periodontal tissues is to have sufficient concentrations of ideal factors at the healing site. Some factors that have been considered as attractive candidates for delivery to these sites are discussed next and outlined in Table 72.1.

### Growth Factors

Growth factors have been used to target restoration of tooth-supporting bone, PDL, and cementum. A major focus of periodontal research has evaluated the impact of growth factor applications on periodontal tissue regeneration (reviewed in Giannobile, 1996; Cochran and Wozney, 1999; Anusaksathien and Giannobile, 2002; Nakashima and Reddi, 2003). These reviews describe various delivery systems and applications of growth factors, which are highlighted in Table 72.1. Advances in molecular cloning have made available unlimited quantities of recombinant growth factors for applications in tissue engineering. Recombinant growth factors known to promote skin and bone wound healing, such as PDGFs, insulin-like growth factors (IGFs), fibroblast growth factors (FGFs), and BMPs, have been used in pre-clinical and clinical trials for the treatment of periodontal osseous defects as well as alveolar bone-supporting endosseous dental implants.

#### Platelet-Derived Growth Factor (PDGF)

PDGF is a member of a multifunctional polypeptide family that binds to two cell membrane tyrosine kinase receptors (PDGF-R $\alpha$  and PDGF-R $\beta$ ) and subsequently exerts its biological effects on DNA replication, chemotaxis, extracellular matrix biosynthesis, and blocking growth arrest

(Kaplan *et al.*, 1979; Seppa *et al.*, 1982; Heldin *et al.*, 1989; Rosenkranz and Kazlauskas, 1999). PDGF- $\alpha$  and - $\beta$  receptors are expressed in regenerating periodontal soft and hard tissues (Parkar *et al.*, 2001). In addition, PDGF initiates tooth-supporting periodontal ligament (PDL) cell chemotaxis (Nishimura and Terranova, 1996), mitogenesis (Oates *et al.*, 1993), matrix synthesis (Haase *et al.*, 1998), and attachment to tooth dentinal surfaces (Zaman *et al.*, 1999). Local topical application of PDGF alone or in combination with insulin-like growth factor-1 (IGF-1) results in repair of periodontal tissues, including bone and PDL (Lynch *et al.*, 1989, 1991; Rutherford *et al.*, 1992; Giannobile *et al.*, 1994, 1996).

### Bone Morphogenetic Proteins (BMPs)

The human genome encodes at least 20 BMPs (Reddi, 1998) that are multifunctional polypeptides belonging to the TGF- $\beta$  superfamily of proteins (Wozney *et al.*, 1988). BMPs bind to type I and II receptors that function as serine-threonine kinases. The type I receptor protein kinase phosphorylates intracellular signaling substrates. The phosphorylated BMP-signaling Smads enter the nucleus and initiate the production of bone matrix proteins, leading to bone morphogenesis. The most remarkable feature of BMPs is the ability to induce *de novo* bone formation (Urist, 1965). BMPs are not only powerful regulators of cartilage and bone formation during embryonic development and regeneration in postnatal life, but also participate in the development and repair of other organs, such as the kidney and brain (Reddi, 2001). Studies have demonstrated the expression of BMPs during tooth development and periodontal repair, including in alveolar bone (Aberg *et al.*, 1997; Amar *et al.*, 1997). Investigations in animal models have shown the potential repair of alveolar bony defects around teeth and dental implants using BMP-2, -4, -7, and -12 (Lutolf *et al.*, 2003; Wikesjo *et al.*, 2003, 2004). In a recent clinical trial, BMP-2 delivered via a bioabsorbable collagen sponge promoted bone formation in buccal wall extraction socket defects when compared to collagen sponge alone (Fiorellini *et al.*, 2005). Furthermore, BMP7, also known as osteogenic protein-1, stimulates bone regeneration around teeth and endosseous dental implants and in maxillary sinus-floor-augmentation procedures (Rutherford *et al.*, 1992; Giannobile *et al.*, 1998; van den Bergh *et al.*, 2000).

### Factors Being Considered Based on Their Suggested Role During Development of Periodontal Tissues

#### Epithelial-Like Products

It is well established that epithelial-mesenchymal (E-M) interactions are required for development of the tooth crown (enamel-ameloblasts; dentin-odontoblasts). The reader is referred to the website <http://bite-it.helsinki.fi/> for a comprehensive list of signaling molecules and target

genes expressed during crown development. Based on this knowledge, some success has been achieved toward regeneration of tooth structures in animal models, predominantly crowns, using a stem cell approach, mixing epithelial cells with mesenchymal cells at various stages of differentiation (Fong *et al.*, 2005; Zhang *et al.*, 2005). Accumulating data suggest that E-M interactions may also be involved in formation of periodontal tissues. In fact, a product currently marketed for use in regenerating periodontal tissues, Emdogain® (EMD, Straumann Biologics, Waltham, MA), is based on this concept. EMD is an extract of low-molecular-weight proteins derived from porcine tooth germs. The predominant protein in this extract is amelogenin, although it has been reported to contain several other factors, including proteolytically cleaved and alternatively spliced products of the amelogenin gene, i.e., leucine-rich amelogenin (LRAP) and tyrosine-rich amelogenin (TRAP), and ameloblastin and TGF- $\beta$  (transforming growth factor  $\beta$ ). *In vitro*, EMD, LRAP, TRAP, amelogenin, ameloblastin, and TGF- $\beta$  have been shown to affect the behavior of mesenchymal cells, including reports of enhancing cell proliferation and cell adhesion (EMD) and altering genes associated with mineralization (EMD, LRAP, TRAP, amelogenin, ameloblastin, and TGF- $\beta$ ), while *in vivo* EMD has been shown to have positive clinical outcomes when used for regenerating lost periodontal tissues, although the results are often limited and not predictable (see reviews Esposito *et al.*, 2003; Giannobile and Somerman, 2003; Venezia *et al.*, 2004; Bartlett *et al.*, 2006; Heden and Wennstrom, 2006).

In spite of the fact that a product is used clinically based on the concept that E-M interactions are involved in development of periodontal tissues, it is still unclear as to whether or not E-M communications are required for development of periodontal tissues and, hence, their function in regeneration of periodontal tissues. Much of this doubt is based on the fact that the known roles for amelogenin and ameloblastin, secreted by ameloblasts, are as regulators of enamel formation via controlling crystal growth and structure. This has been highlighted by the murine phenotypes reported in overexpression and/or null for amelogenin or ameloblastin (Gibson *et al.*, 2001; Paine *et al.*, 2003; Paine and Snead, 2005). Mice null for amelogenin form enamel, but the crystal structure of the formed enamel lacks structure. An interesting finding was then noted: increased root resorption in amelogenin-null mice, leading Kulkarni and his group to propose that amelogenin-like products, perhaps LRAP, have a protective effect on cementoblasts by decreasing the expression of RANKL, an activator of osteoclasts (Gibson *et al.*, 2001; Hatakeyama *et al.*, 2003, 2006).

One critical piece of information required is the identification of binding sites for amelogenin-like molecules and/or other epithelial derived factors on mesenchymal cells. Toward that end, Tompkins *et al.* (2006) reported the identification of a receptor for LRAP on the cell surface of myoblasts, LAMP-1, lysosomal-associated membrane protein-1,

while Paine *et al.* reported that amelogenin bound to LAMP-3 in association with lysosomes (Wang *et al.*, 2005). The latter group proposed that LAMP-3 functions to degrade amelogenin. In contrast, Tompkins *et al.* propose that LRAP interacts with LAMP-1 on the cell surface and that this interaction results in downstream signaling events. Further studies, ongoing, will assist in clarifying the significance of amelogenin-like molecules and other epithelial-like molecules in regulating periodontal/root formation and, subsequently, periodontal regeneration.

### Phosphates

Several reports have demonstrated that alterations in phosphate/pyrophosphate regulation in both humans and animals have profound effects on bone homeostasis (Terkeltaub, 2001). Further, there is mounting evidence that inorganic phosphate (Pi), beyond its known role as a physiochemical regulator of mineralization, may control mineralization via signaling pathways. For example, mice null for tissue nonspecific alkaline phosphatase (TNAP), an enzyme that hydrolyzes pyrophosphate (PPi) to phosphate (Pi), are osteopenic and exhibit minimal or no cementum formation. The lack of cementum formation prevents the insertion of PDL fibers into cementum and surrounding bone, resulting in exfoliation of teeth. This tooth phenotype is noted in both animals and humans with mutations in TNAP. Importantly, there is a dental-specific form, odontohypophosphatasia, marked by abnormalities limited to teeth (Whyte, 2002). In contrast to TNAP, there are two genes and their products, PC-1 (nucleoside triphosphate pyrophosphohydrolase) and ANK, a protein of a mouse progressive ankylosis gene (ANKH — human homolog), that regulate PPi levels. ANK is a transmembrane protein regulating the transport of PPi from intracellular to extracellular locations. PC-1 regulates PPi levels in matrix vesicles and in extracellular compartments.

Mice with mutations in PC-1 or ANK have low levels of PPi, and this results in pathological ectopic calcification, including aortic valves and joints, mimicking an arthritic condition. In fact, mice with PC-1 mutation have been called tiptoe-walking (ttw) mice, since the severe ectopic calcification of joints results in an inability to walk. Mutated PC-1, with decreased extracellular pyrophosphate (ePPi) levels, has been linked to individuals affected with severe periarticular and vascular calcification (Rutsch *et al.*, 2001). Mutations in the human ANK gene have been identified in patients with a rare disorder, autosomal-dominant cranio-metaphyseal dysplasia. Affected individuals have marked osteosclerosis of craniofacial bones, often with neurological defects and flaring of metaphyses of long bones; but often, extracranial skeleton and joints are otherwise not affected (Reichenberger *et al.*, 2001). In terms of a tooth phenotype, Nociti *et al.* (2002) reported a marked increase in cementum formation in mice with either ANK/ANK or PC-1 mutations vs. wild-type control (greater than 10× increase); however, this was not associated with ectopic calcification or

decreased PDL space, and the surrounding alveolar bone appeared normal. To date, it is not established whether a tooth phenotype is noted in individuals with mutations in PC-1 or ANKH although a recent case report suggests a tooth phenotype (Zhang *et al.*, 2007).

The specific tooth phenotypes noted in murine models and human with mutations in TNAP have led us to hypothesize that periodontal tissues are phosphate-sensitive tissues, relative to several other tissues within the body. It is our belief that research targeted at understanding the genes/proteins and signaling pathways involved in phosphate-mediated cementum formation will result in the development of novel factors for use in delivery to sites for regeneration of lost periodontal support.

### Anabolic Factors

*Parathyroid hormone*, PTH, has been shown to have both catabolic and anabolic effects on osteoblastic-/cementoblastic-like cells (Fiaschi-Taesch and Stewart, 2003; Boabaid *et al.*, 2004). One of the mechanisms contributing to these activities include the ability of PTH to enhance the expression of RANKL in both osteoblasts and cementoblasts. RANKL is a key activator of osteoclasts via its binding to RANK on the cell surface osteoclasts. PTH given intermittently *in vitro* or *in vivo* (animal models and humans) results in enhanced bone formation. This knowledge has resulted in the use of PTHC (Forteo®) for treatment of severe osteoporosis. Forteo® [teriparatide (rhDNA origin) injection] contains human PTH (1-34) (Eli Lilly & Co.). It is tempting to speculate that controlled (intermittent) release of PTH or other anabolic factors at sites of periodontal destruction in humans would have very positive outcomes. Toward that end, Barros *et al.* (2003), using ligatures to induce periodontitis around first molars in rats, demonstrated that intermittent PTH, delivered subcutaneously over a 30-day period, protected the tooth site from periodontitis-induced bone resorption, noted in vehicle-treated rats. Currently, several groups are working on local delivery of PTH as well as other anabolic agents.

## III. CURRENT APPROACHES IN PERIODONTAL TISSUE ENGINEERING

### Role of Cells Within the Local Region

It has been known for decades that cells within the periodontium have the potential, when appropriately stimulated, to promote formation of new bone, cementum, and functional periodontium. This knowledge has led to considerable basic, translational, and clinical research focused on defining the signals and identifying the cells required to promote regeneration of periodontal tissues, with the ultimate goal of developing successful and predictable therapies.

Once the disease is under control, a viable approach is to promote the cells remaining at the site, in a manner to

regenerate lost structures. Cells within the local region considered to play key roles in regenerating lost tissues include inflammatory cells, cells within the vasculature, PDL fibroblasts, osteoblasts, cementoblasts, and epithelial cells (see reviews: Gould *et al.*, 1980; McCulloch, 1985, 1995; Melcher, 1985; Bartold *et al.*, 2000; Nanci and Bosshardt, 2006). Factors released by inflammatory cells provide the motivation for fibroblasts and cells from the vasculature to begin the wound-healing process. Beyond the ability of a small population of cells within the PDL region to function as osteoblasts and/or cementoblasts (see later), these cells must control the balance between soft (PDL formation) and hard tissues (bone/cementum). Thus, a targeted area of research has emerged toward identifying both the promoters of mineralization as well as the negative regulators, allowing for formation of a functional PDL.

In addition, as also discussed later, understanding the factors and cells involved during development of periodontal tissues has provided clues to the cell types needed to promote regeneration of these tissues. For example, follicle cells, associated with the developing tooth and of mesenchymal origin, are considered to have the capacity to become cementoblasts, PDL fibroblasts, or osteoblasts, depending on the stimuli within the local region (Hakki *et al.*, 2001; Wise *et al.*, 2002; Zhao *et al.*, 2002; Zeichner-David *et al.*, 2003). However, when cementoblasts and follicle cells in PLGA polymer sponges were delivered to periodontal defects in rats, only cementoblasts provided an environment that promoted formation of new bone, cementum, and a PDL. In contrast, follicle cells under these same conditions inhibited mineral formation when compared with the vehicle control or cementoblasts. These results led M. Zhao *et al.* (2004) to hypothesize that follicle cells produce factors that control the extent of mineral formed and thereby allow for development of soft tissue–hard tissue interfaces during formation of the root/periodontium. Thus, defining the factors that trigger follicle cells to mature toward an osteoblast/cementoblast phenotype vs. PDL fibroblasts should provide information as to the regulators required for promoting PDL cells and other cells in the local environment to repair lost structures. As discussed earlier, some of the viable factors being considered include epithelial-like products produced by ameloblasts and/or Hertwig's epithelial root sheath (HERS), a doubled-layered sheath formed after the crown develops. The cells in this latter region proliferate apically and function to direct root morphogenesis. Products secreted by HERS, including BMPs, have been thought to stimulate follicle cells to develop into cementoblasts. An alternative suggestion is that HERS cells undergo transformation from an epithelial cell type to a mesenchymal cell type, i.e., cementoblast (for discussions on this topic, see Slavkin *et al.*, 1989; MacNeil and Somerman, 1999; Bosshardt and Nanci, 2004). Another aspect of the HERS that needs some attention is that as the root/periodontal region matures, remnant epithelial cells from HERS, called

*epithelial rest cells of Malassez* (ERCM), are noted within the PDL region. It has been suggested that these remnant cells have a role in wound healing, and thus some investigators have been working on ascertaining the factors secreted by ERCM (Hasegawa *et al.*, 2003).

### Stem Cells for Periodontal Tissue Engineering

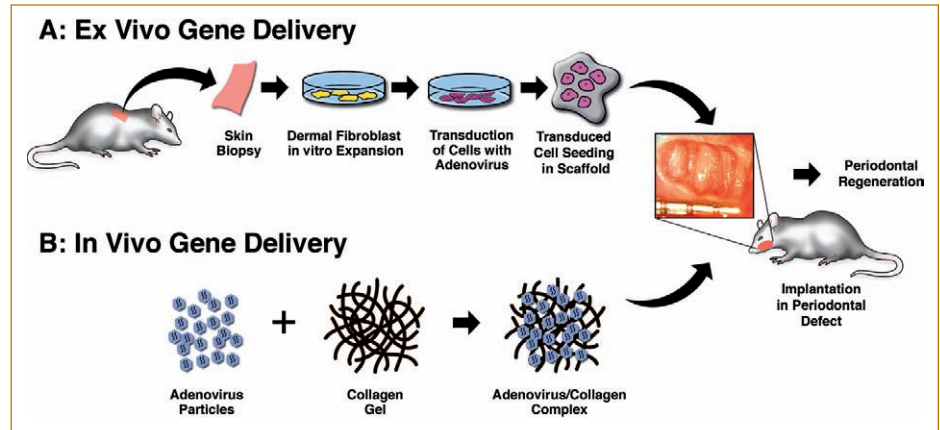

The self-renewing stem cells (also called *mesenchymal stem cells*, MSCs) are capable of promoting tissue repair and regeneration. Recent research has shown that MSCs are present in mature dental tissues (Gronthos *et al.*, 2000; Miura *et al.*, 2003; Seo *et al.*, 2005). This stimulated some investigators to test the possibility of using stem cell–based therapies to regenerate the damaged periodontal tissues as a result of severe periodontitis (Miura *et al.*, 2004; Seo *et al.*, 2004).

MSCs have been identified in various human dental tissues, including adult third molars (dental pulp stem cells, DPSCs) (Gronthos *et al.*, 2000), exfoliated deciduous teeth (stem cells from human exfoliated deciduous teeth, SHED) (Miura *et al.*, 2003), and adult periodontal ligament (periodontal ligament stem cells, PDLSCs) (Seo *et al.*, 2004). Similar to the characterization of bone marrow stromal stem cells (BMSSC), these cells were identified by their capacity to form colony-forming units–fibroblast, (CFU-F) (Castro-Malaspina *et al.*, 1980). In addition, STRO-1, the putative stem cell marker, was also expressed in these dental-derived stem cells. Unlike DPSCs or SHED, which are derived from dental pulps and therefore could be characterized by the expression of odontoblast-specific protein, dentin sialophosphoprotein (DSPP) (MacDougall *et al.*, 1997; Feng *et al.*, 1998), there are no specific markers to characterize PDLSC. To date, scleraxis, a tendon-specific transcription factor, has been used to characterize PDLSC because of the similarity in collagen composition between PDL and tendon (Brent *et al.*, 2003).

Under proper inductive conditions, PDLSC has the capacity to differentiate toward different lineages, such as lipid-containing fat cells, and to form mineralized nodules as well as cementum-/PDL-like structures (Seo *et al.*, 2004). Sharpey's fibers were also observed to connect newly formed cementum to type I collagen-positive PDL-like tissue within the transplant.

Animal models and preliminary clinical trials have demonstrated great potential for the use of BM SSCs in treating various diseases (Azizi *et al.*, 1998; Hofstetter *et al.*, 2002; Toma *et al.*, 2002; Zhao *et al.*, 2002; Fuchs *et al.*, 2003; Gojo *et al.*, 2003), including cranial defects (Krebsbach *et al.*, 1998; Schantz *et al.*, 2003). It has been reported that porcine bone marrow progenitor cells seeded onto polyglycolide-*co*-lactide (PLGA) scaffolds can be used to repair critical defects in the pig mandible (Abukawa *et al.*, 2004). Toothlike structures were also generated in the omenta of rats using pig- and rat-tooth bud cells seeded onto polyglycolide (PGA) and PLGA scaffold materials (Young *et al.*,

**FIG. 72.2.** Gene delivery approaches for periodontal-tissue engineering. (A) *Ex vivo* gene delivery involves the harvesting of tissue biopsies, expansion of cell populations, genetic manipulations of cells, and subsequent transplantation to periodontal osseous defects. (B) *In vivo* gene transfer involves the direct delivery of growth factor transgenes to the periodontal osseous defects. Reproduced from Ramsey *et al.* (2006) with the permission of Elsevier, Inc.

2002). By coordinating the timing of tooth and bone formation, a tooth–bone hybrid tissue joined by periodontal ligament was bioengineered recently (Young *et al.*, 2005). All of these have facilitated the idea of using MSCs to regenerate cementum, PDL, and bone lost as a result of advanced periodontitis. Kawaguchi *et al.* (2004) used *ex vivo* expanded BMSSC mixed with atelocollagen to regenerate experimental class III furcation defects in beagle dogs. One month after transplantation, the defects were almost completely covered with new cementum, regenerated periodontal ligament, and alveolar bone. In another study, cultured human PDLSCs were transplanted into surgical defects at the periodontal region of mandibular molars in immunocompromised rats (Seo *et al.*, 2004). PDL-like tissue was formed connecting alveolar bone and cementum surfaces. Thus it is promising that periodontal tissue could be regenerated by obtaining MSCs, which are then expanded *ex vivo* and transplanted to the areas where periodontal reconstruction is indicated.

### Limitations of Topical Growth Factor Administration

Topical delivery of growth factors to periodontal wounds has shown promising results, yet insufficient for the stimulation of consistent periodontal tissue engineering (Cochran and Wozney, 1999; Camelo *et al.*, 2003). Growth factor proteins, once delivered to the target site, tend to suffer from lability, due primarily to proteolytic breakdown, receptor-mediated endocytosis, and solubility of the carrier (Anusaksathien and Giannobile, 2002). Because the half-lives of GFs are transient, the period of exposure may not be sufficient to act on osteoblasts, cementoblasts, or PDL cells. Therefore, different methods of growth factor delivery need to be considered (Anusaksathien *et al.*, 2005).

Investigations for periodontal bioengineering have examined a variety of methods combining delivery vehicles, such as scaffolds, with growth factors to target the defect site in order to optimize bioavailability (Lutolf and Hubbell, 2005). The scaffolds are designed to optimize the dosage of

the growth factor and to control its release pattern, which may be pulsatile, constant, or time programmed (Babensee *et al.*, 2000). Additionally, the kinetics of the release and the duration of the exposure of the growth factor may be controlled (Hutmacher *et al.*, 2000).

To address transient bioactivity of GF peptides *in vivo*, gene therapy using a vector encoding the growth factor has been utilized to stimulate tissue regeneration. So far, two main strategies of gene vector delivery have been applied to periodontal tissue engineering. Gene vectors can be introduced directly to the target site (*in vivo* approach) (Jin *et al.*, 2004), or selected cells can be harvested, expanded, genetically transduced, and then reimplanted (*ex vivo* technique) (Jin *et al.*, 2003) (Fig. 72.2). *In vivo* gene transfer involves the insertion of the gene of interest directly into the defect, promoting genetic modification of the target cell. *Ex vivo* gene transfer includes the incorporation of genetic material into cells exposed from a tissue biopsy, with subsequent reimplantation into the recipient.

### Gene Delivery for Periodontal Tissue Engineering

Gene transfer strategies for tissue engineering have demonstrated success in healing soft-tissue wounds such as skin lesions (Crombleholme, 2000). Both PDGF plasmid (Hijawi *et al.*, 2004) and Adenovirus (Ad)/PDGF gene delivery (Printz *et al.*, 2000) has been evaluated in preclinical and human trials. However, the latter has been able to exhibit more robust results favorable for clinical use (Gu *et al.*, 2004).

Early studies in dental applications using recombinant adenoviral vectors encoding PDGF showed that vector constructs can transduce cells derived from the periodontium (osteoblasts, cementoblasts, PDL cells, and gingival fibroblasts) (Giannobile *et al.*, 2001; Zhu *et al.*, 2001). Additionally, Chen and Giannobile (2002) were able to demonstrate the sustained effects of adenoviral delivery of PDGF for a better understanding of extended PDGF signaling. In an *ex vivo* investigation by Anusaksathien *et al.* (2003), it was

shown that the expression of PDGF genes was prolonged for up to 10 days in gingival wounds. Adenovirus encoding PDGF-B (Ad/PDGF-B) transduced gingival fibroblasts and enhanced defect fill by induction of human gingival fibroblast migration and proliferation. However, in another study, continuous exposure of cementoblasts to PDGF-A had an inhibitory effect on cementum mineralization, possibly via the up-regulation of osteopontin (OPN) and subsequent enhancement of multinucleated giant cells (MNGCs) in cementum-engineered scaffolds. Furthermore, Ad/PDGF-1308 (a dominant-negative mutant of PDGF) inhibited mineralization of tissue-engineered cementum, possibly due to down-regulation of bone sialoprotein (BSP) and osteocalcin (OC), with a persistence of stimulation of MNGCs. These findings suggest that continuous exogenous delivery of PDGF-A may delay mineral formation induced by cementoblasts, while PDGF is clearly required for mineral neogenesis (Anusaksathien *et al.*, 2004).

Jin *et al.* (2004) demonstrated that direct *in vivo* gene transfer of PDGF-B stimulated tissue regeneration in large periodontal defects. Descriptive histology and histomorphometry revealed that human PDGF-B gene delivery promotes the regeneration of both cementum and alveolar bone, while PDGF-1308, has minimal effects on periodontal-tissue regeneration.

Jin *et al.* (2003) demonstrated that *ex vivo* delivery of BMP7-transduced fibroblasts in a gelatin matrix promoted periodontal tissue repair in large mandibular periodontal bone defects. BMP-7 gene transfer not only enhanced alveolar bone repair, it also stimulated cementogenesis and PDL fiber formation. Of interest, the alveolar bone formation was found to occur via a cartilage intermediate. However, when genes encoding the BMP antagonist noggin were delivered, inhibition of periodontal tissue formation resulted (Jin *et al.*, 2004). Dunn *et al.* (2005) recently demonstrated that direct *in vivo* gene delivery of BMP-7 in a collagen matrix promoted regeneration of extraction socket bone defects around dental implants. These experiments provide promising evidence showing the feasibility of both *in vivo* and *ex vivo* gene therapy for periodontal tissue regeneration and peri-implant osseointegration.

### Scaffold Materials for Tissue Engineering of Periodontal Tissues

Scaffolds are three-dimensional structures that provide an environment for healing and/or regeneration of damaged tissues and therefore have gained attention as attractive candidates for use in repair/regeneration of tissues (Nakashima and Akamine, 2005). Today, the choice of scaffold material has become wide-ranging in terms of chemical formulations and material properties (Garg, 1999; Reynolds *et al.*, 2003; Branfoot, 2005; Taba *et al.*, 2005). Regardless of the scaffold material selected, there are basic requirements these materials must satisfy in order to achieve successful tissue repair. They must be biocompatible, able to support

cell adhesion/differentiation/proliferation, and resorbable by the body. Those designed for delivery of biological mediators, cells/genes/proteins, to the wound site must be sustained at the site for a sufficient time to interact with cells in the local environment. Scaffold materials that have applicability to periodontal tissue repair include human bone derivatives, bioceramics, synthetic polymers, and composites thereof (Caffesse *et al.*, 2002; Reynolds *et al.*, 2003; Wang *et al.*, 2005). Please refer to Table 72.2 for a summary of current applications of scaffold materials in periodontal treatment therapies. For the most part, clinically accepted scaffold materials for treating periodontal diseases are those that perform well in promoting bone regeneration. However, the success of these materials in regenerating periodontal ligaments, bone, and cementum remains limited; furthermore, outcomes are not predictable (Caffesse *et al.*, 2002; Wang *et al.*, 2005). The next generation of scaffold materials for regenerating the entire periodontium may require that these materials have the capacity to deliver appropriate biological mediators in a specified temporal-spatial fashion.

### Human Bone Derivatives

Bone derivatives include autografts and allografts. Autografts, obtained from the same individual, are used to augment bone as needed for implants and also at sites of periodontal defects. While good results are achieved, especially for bone/ridge augmentation, the procedures can be invasive and require a healing phase and a second surgery (Garg, 1999; Wang *et al.*, 2005). Allografts are human bones that may come in powdered form or in fragments of cortical, cancellous, and cortical-cancellous bone of various sizes. Because allografts are osteoconductive and, properly sterilized, pose few adverse effects on immuno-response, they are widely used for regenerating lost bone tissues resulting from periodontal diseases. Clinical applications using commercial allografts include fenestrations, periodontal defects, and ridge augmentations.

Allografts can also be used in demineralized form, also known as demineralized bone matrix, where the mineral is dissolved away, leaving behind collagen, BMPs, and noncollagenous proteins. New bone is generated around demineralized allografts by osteoinduction, considered to be due to the presence of BMPs. While allografts have gained clinical acceptance, the results are neither consistent nor sufficient for the replacement of large defects.

### Bioceramics

Calcium phosphate, mainly as tricalcium phosphate (TCP) and hydroxyapatite (HA), have been used for bone regeneration applications because they are highly osteoconductive materials. Tricalcium phosphate is more readily resorbed than hydroxyapatite (Garg, 1999). Studies have established pure TCP or biphasic TCP/HA as viable graft

**Table 72.2.** Summary of scaffold materials being used/evaluated for treating periodontal defects

<i>Scaffold material</i>	<i>Chemical constituents</i>	<i>Characteristics favorable for regeneration therapy</i>	<i>Treatments</i>
Autografts	Calcium phosphate (HA), collagen, growth factors (e.g., BMP), etc.	Highly osteogenic	Osseous defects
Allografts (in combinations)			
Freeze-dried bone	May contain calcium phosphate (HA), collagen, growth factors (e.g., BMP), etc.	Osteoconductive, osteoinductive	Osseous defects
Demineralized freeze-dried bone	May contain collagen, growth factors (e.g., BMP), etc.	Osteoconductive	Osseous defects
Xenografts	Calcium phosphate (HA), some with added factors (e.g., synthetic cell-binding peptides)	Osteoconductive, high porosity, allowing tissue ingrowth	Osseous defects
Tricalcium phosphate (TCP) or biphasic TCP/HA (BCP)	Calcium phosphate: TCP (and HA)	Osteoconductive, resorbable	Osseous defects
Coral-derived HA	Calcium phosphate (HA)	Osteoconductive, high porosity, allowing tissue ingrowth	Osseous defects
Coral	Calcium carbonate (aragonite)	Osteoconductive, resorbable, high porosity, allowing tissue ingrowth	Osseous defects
Bioglass	Calcium, phosphorous, sodium, silicon, oxygen	Osteoconductive, resorbable	Osseous defects, ridge augmentation
Resorbable polymers	Polyglycolic acid, polylactic acid, copolymers thereof, some with added factors (e.g., growth factors, BMPs)	Resorbable, can tailor porosity and morphology such as nanofibers	Osseous defects and soft-tissue grafts

materials for use in treating periodontal osseous defects (Garg, 1999). Bovine-derived hydroxyapatite can be fabricated into low-porosity blocks and granules by sintering, or into high-porosity structure by a low-heat alkaline extraction process, also known as xenografts (Caffesse *et al.*, 2002). Since the low-porosity bulk structure poses poor attachment and poor mechanical properties (brittleness), it is not widely applied for treating periodontal defects. Even though the issue of embrittlement is less severe in the granule analog and can be used for ridge augmentation, more porous structures are preferred for periodontal regenerative treatment, including ridge augmentation and osseous defects. The high porosity appears to be the key to an effective medium for cell/bone ingrowth and integration. In addition, porous hydroxyapatite has been studied as a scaffold material for use in guided tissue regeneration (to exclude epithelial downgrowth).

Using collagen and other barrier membranes in conjunction with porous xenografts and other graft materials

has yielded some success, but with variable results, depending on the type of defect (Caffesse *et al.*, 2002; Reynolds *et al.*, 2003; Eppeley *et al.*, 2005; Wang *et al.*, 2005). Further, there are mixed reports as to whether or not results are improved when both a graft and a membrane are used vs. the use of either one alone (Reynolds *et al.*, 2003; Hartman *et al.*, 2004; Sculean *et al.*, 2005; Wang *et al.*, 2005).

Porous scaffolds have also been fabricated from corals. Corals skeletons, which are made of highly porous calcium carbonate, can be converted to hydroxyapatite via high-temperature treatment. The conversion process retains the porous structure, which enables bone ingrowth similar to that of porous xenograft. Alternatively, corals can be used in their native calcium carbonate form as a scaffold for use in bone regeneration. The calcium carbonate is highly resorbable and is readily osseointegrated. As a result, coral scaffolds have broad clinical applications for use in bone regeneration such as spinal disc fusions and regeneration of femur bone, as well as periodontal osseous defects (Eppeley

*et al.*, 2005). Results for periodontal defects are considered comparable to those for other allograft/alloplast materials (Garg, 1999). Further, applying coral scaffolds to guided tissue regeneration indicated enhancement of new bone formation, though it is unclear if this enhancement was due to the osteoconductivity of the coral scaffold (Reynolds *et al.*, 2003; Wikesjö *et al.*, 2003; Koo *et al.*, 2005).

Another class of bioceramics is bioactive glass, which is composed of calcium, phosphate, sodium, and silicon. Bioactive glass is not porous and therefore is not susceptible to any tissue ingrowth. However, its high-bioactivity surface is favorable for cell and tissue attachment. Commonly introduced to the wound site as particulates, the glass surface is readily colonized by osteogenic cells and then by a collagen network attaching the particulate to the surrounding tissue, enabling further bone growth and attachment on the particulates. Bioactive glass has been reported to be of value in treating intrabony defects (Garg, 1999; Park *et al.*, 2001).

### Synthetic Polymers

The most common polymer scaffold materials are polyglycolic acid (PGA), polylactic acid (PLA), and their copolymers (PLGA). These polymers are resorbable, with the resorption rate controllable by varying the molecular weight (Wu, 1995). Because of the ability to alter properties associated with biodegradability and porosity, polymers have a vast range of clinical applications, from use as barrier membranes in guided tissue regeneration to use as delivery systems for release of factors and/or cells to periodontal defects (Abukawa *et al.*, 2006). *In vitro* and *in vivo* studies using SCID mice have shown that PLGA is a viable scaffold material to deliver cementoblast cells as a means to regenerate periodontal tissues (Jin *et al.*, 2003; Zhao *et al.*, 2004). Similarly, stem cell studies such as those described earlier have used PLGA exclusively as the scaffold on which cells were seeded (Abukawa *et al.*, 2004; Young *et al.*, 2005). Furthermore, approaches to utilize PLGA as time-controlled release of growth factors are in active investigation. A study by Wei and coworkers (2006) demonstrated that the release of PDGF-BB could be controlled temporally by encapsulating PDGF-BB in PLGA microspheres, which in turn entrapped in a nanofibrous poly(L-lactic acid) (PLLA) scaffold. Sustained release of bioactive PDGF-BB was shown to be controllable from days to months by varying the molecular weight of the microspheres (Wei *et al.*, 2006).

In addition to PLA-PGA polymer systems, other formulations have shown potential as scaffold systems for use in periodontal tissue regeneration. A study by Nakahara *et al.* (2003) demonstrated successful fabrication of a collagen scaffold construct that sandwiched basic fibroblast growth factor (bFGF)-containing gelatin microspheres within the

collagen scaffold and applied this to periodontal defects of beagle dogs. The results indicated formation of new bone, cementum, and PDL. In another approach, Hasegawa *et al.* (2005), using an athymic rat periodontal defect model, reported success in regenerating new bone, cementum, and a functional PDL by delivery of PDL cell sheets to the defective sites. The cell sheets were developed *in vitro* by applying a unique method to control cell adhesion by modifying culture temperature conditions and using a surface-grafted temperature-response polymer, poly(*N*-isopropylacrylamide) (PIPAAm).

The future of successful periodontal tissue engineering may very well lie in the ability to utilize effectively these biodegradable polymers as delivery vehicles for appropriate cells and/or factors. Improved delivery systems coupled with enhanced understanding of the mechanistic/biological regulators of tissue formation should result in better and more predictable treatment therapies within the next decade.

## IV. FUTURE DIRECTIONS

The emerging new technologies and major advances in our understanding of the cell/molecular factors controlling the function of cells within the periodontium, linked with improvements in scaffold design for local controlled delivery, and a new appreciation for the capacity of adult cells to function as stem cells have resulted in improvements in our approach to treating periodontal diseases. Nevertheless, predictable regenerative therapies have not kept up with the advances in implant therapy. As a consequence, it is often more attractive to replace severely damaged periodontal tissues with implants than to attempt to regenerate lost structures. Implants are not always the best treatment, for many reasons, among them location, inadequate bone, and lack of a PDL. Thus, ideally, one would like to be able to restore the “natural” tooth.

This chapter has focused on restoring periodontal tissues as one aspect of the long-term goal of restoring the whole tooth. The goal of predictably engineering periodontal tissues requires a strong collaboration amongst a multitude of disciplines, e.g., cell/molecular biologists, computational scientists, bioengineers, geneticists, chemists, and clinicians. The various pieces of information that are missing include (a) detailed information on the stem cell properties of periodontal tissues; (b) identifying the trigger factors, likely to be a well-orchestrated delivery of several factors over a period of time; (c) designing scaffolds that can deliver these factors over time; and (d) recognizing variability in host response to factors/cells. Advances in all of these areas are moving forward and have already resulted in improved approaches for restoring lost periodontal tissues.

## V. ACKNOWLEDGMENTS

The authors would like to thank Luke Wallace for assisting in preparation of the figures and critical review of the chapter by Brian Foster and Eugenie Fyfe. Reviews are cited instead of individual papers in some areas due to

the limited space. The studies were supported by the following NIH/NIDCR grants: DE13047(MJS), DE15109(MJS), DE016619(WVG), DE09532(MJS and WVG), and DE13397 (MJS and WVG).

### I. INTRODUCTION: LUNG BIOLOGY AND OPPORTUNITIES FOR REGENERATION OF THE LUNG

Acute and chronic pulmonary disorders are common causes of morbidity and mortality throughout life. Under normal circumstances, the human lung maintains respiration under a wide range of environmental and exertional conditions. The lung is capable of remarkable repair following injury caused by infection, inhaled toxicants, or resection. Since respiration is solely dependent on lung structure and function, failure to form adequate lung tissue during morphogenesis and loss of lung tissue related to acquired or inherited pulmonary disorders are common clinical occurrences that are often life threatening. Considerable interest has been generated in understanding the biological events underlying the repair or regeneration of lung tissue. Understanding the principles determining normal lung formation and repair will provide insights into the pathogenesis of pulmonary disease and open new avenues for therapy designed to enhance normal repair processes in the lung. Progress has been made in identifying critical

processes in stem cell and progenitor cell biology in general as well as those active during lung formation, differentiation, and repair. In this chapter, the identity and molecular processes regulating progenitor cells during lung morphogenesis and repair are discussed in relationship to research supporting opportunities for the application of endogenous and exogenous cells for repair and regeneration of the lung.

### II. COMPLEXITY OF LUNG STRUCTURE PRESENTS A CHALLENGE FOR TISSUE ENGINEERING

The formation of the lung occurred relatively late in evolution, being required for adaptation to air breathing needed to support the respiratory requirements of vertebrates of diverse sizes. The lung is not required for normal organogenesis of other organs. There is no evidence that it produces substances required for development or function of other organs. Its function is inherent in its structure. The lung is a remarkably complex organ, consisting of multiple cell types that are precisely arranged on complex scaffold

support of conducting airways (trachea, bronchi, and bronchioles) that lead to alveoli, wherein an elastin-rich network supports the epithelial-lined saccules, perfused by an extensive vascular bed. Alveolar walls are lined by type I and type II epithelial cells that are uniquely suited for gas exchange and surfactant production, respectively. Since epithelial surfaces of the lung are exposed directly to environmental gases and particles, effective innate and adaptive immunity and mucociliary clearance systems have evolved to maintain patency and sterility of the lung. The adult human lung contains 300 million to 500 million alveoli, creating an extensive gas exchange region, the area of which changes dynamically during the respiratory cycle. The hydrated epithelial surfaces of the lung are in direct contact with environmental gases, creating surface tension at the air-liquid interface that is mitigated by the continuous presence of pulmonary surfactant. Surfactant, consisting primarily of phospholipid- and surfactant-associated proteins, is required for maintenance of lung volumes during the cyclical contraction and expansion of the lung during ventilation. Maintenance of lung structure, mucociliary clearance, host defense, and surfactant homeostasis as well as the pulmonary circulation are dependent on distinct cell types. The lung contains a number of endogenous pulmonary cell types and marrow-derived cells, including dendritic cells, macrophages, polymorphonuclear leukocytes, lymphocytes, eosinophils, and mast. The remarkable complexity of structure and the ongoing requirements for lung function greatly complicate the application of strategies for cell and organ replacement other than by the transplantation of normal lung tissue. While it is presently not possible to engineer tissue replacements capable of gas exchange, knowledge regarding the cells and molecular events controlling lung organogenesis and function will likely enhance strategies to control cellular processes that might be used for future cell- or tissue-based therapies for lung disorders.

### III. LUNG MORPHOGENESIS

#### Commitment and Restriction of Pulmonary Cells in the Foregut Endoderm

Progenitor cells forming the respiratory epithelium are derived from foregut endoderm. Their precursors are first identified by the expression of thyroid transcription factor-1 (TTF-1) along the anterior-ventral region of the foregut tube, being recognized between E9 and E10 in the developing mouse (four to five weeks of gestation in the human) as the lung primordia form (Lazzaro *et al.*, 1991). Progenitor cells lining the pharyngeal diverticulum form the tracheal-esophageal region. The epithelial cells form the trachea and bronchi and extend into the splanchnic mesenchyme. Regions of foregut endoderm are prespecified before the appearance of distinct organs along the foregut tube. The lung buds first appear between the thyroid and liver buds at approximately E9.5 in mouse development. These endoder-

mally derived progenitor cells proliferate. Lung tubules undergo stereotypic branching and budding to form the conducting airways of the fetal lung (Fig. 73.1). The tubules extend into the underlying splanchnic mesenchyme, driven by migrational and proliferative signals from mesenchymal cells in a process that is dependent on production of FGFs (fibroblast growth factors) that bind and activate receptors on the underlying endodermal cells (Cardoso *et al.*, 1997; Warburton *et al.*, 2000; Shannon and Hyatt, 2004). Lung formation has been divided into distinct structural epochs that are based on anatomic changes shared during vertebrate lung morphogenesis. The general processes involved are highly conserved, but they vary temporally and spatially among diverse species. These epochs are useful in understanding the genes and processes that occur sequentially during lung morphogenesis and are also useful in understanding the pathogenesis of congenital malformations that lead to lung hypoplasia or malformations commonly seen in newborn infants. Early defects in progenitor cell differentiation, survival, and proliferation can profoundly disrupt subsequent morphogenesis, leading to severe and life-threatening pulmonary malformations, including lung agenesis-hypoplasia, diaphragmatic hernia, tracheal-esophageal fistula, and cystadenomatoid malformations, among others. Figure 73.1 describes the epochs based on events occurring during mouse lung morphogenesis that are shared in mouse and human. These events serve to emphasize the complexity of the cellular processes involved in the formation of the lung, some of which are recapitulated during regeneration/engineering of new lung tissue.

TTF-1 is an early marker of the commitment of endodermal cells to pulmonary and thyroid cell lineages, appearing prior to formation of the definitive lung (Lazzaro *et al.*, 1991). Outgrowth and branching of TTF-1 expressing endodermal cells that form the lung requires FGF signaling. Recent studies support the concept that FGF signaling centers from heart and/or from the splanchnic mesenchyme (duration and intensity) along the foregut are critical for lung formation (Serls *et al.*, 2005). The dose and timing of exposure of endodermal precursors to FGF signaling from the cardiac mesenchyme influence the commitment of endoderm to pulmonary lineages (Serls *et al.*, 2005). Cells receiving less FGF stimulation become committed to other organs, including the gastrointestinal tract, liver, and pancreas (Zaret, 2002). In contrast to the lung, thyroid morphogenesis is marked by coexpression of TTF-1 and PAX-8, whereas pulmonary precursors are marked by TTF-1 and FOXA2 (Bohinski *et al.*, 1994; Di Palma *et al.*, 2003). A lung-specific transcription factor has not been identified; thus, at present, the process of lung formation appears to be dependent on direct and indirect interactions of TTF-1 with other transcription factors. Understanding the events critical for restricting cells of the foregut endoderm to pulmonary lineage may be useful in the future in engineering potential progenitor cells into useful pulmonary cells.

## A) Embryonic (E9-E12)

## B) Pseudoglandular (E12-E16)

## C) Canalicular (E16-E17)

## D) Saccular (E17-Birth)

## E) Alveolar (Birth-Adult)

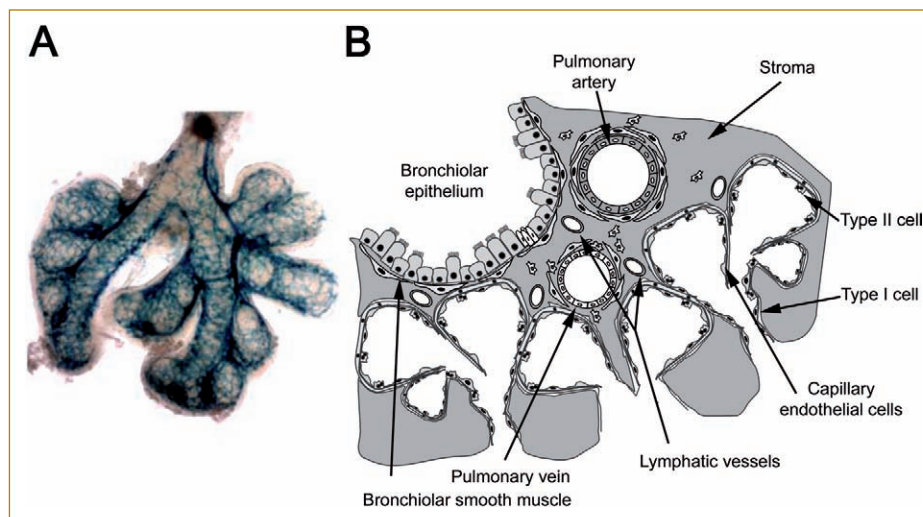

Adult

**FIG. 73.1.** Challenges in tissue engineering of the lung — the complexity of lung morphogenesis. The lung is a large organ, consisting of numerous cell types. Lung morphogenesis has been subdivided into epochs based on anatomic changes that are generally shared among various species during vertebrate morphogenesis. The lung buds emerge from the ventral-medial esophageal region of the foregut endoderm during the embryonic period of development (**A**). The main airways and trachea extend into the splanchnic mesenchyme as branching morphogenesis proceeds during the pseudoglandular period of development (**B**). During the canalicular period (**C**), airway cell differentiation begins in multiple cell types, as evident in the respiratory epithelium, that differ along the cephalo-caudal axis. During the saccular-alveolar period (**D, E**), the peripheral lung grows rapidly and peripheral saccules dilate and septate as they are subdivided into alveoli that comprise the gas exchange region of the lung required for survival after birth. Immunostaining (black cells) for Foxa1 marks the developing pulmonary epithelium or respiratory tubules. Illustrations shown are for mouse lung development.

### The Embryonic and Pseudoglandular Period: Branching Morphogenesis

Lung bud appears on the ventral-medial aspect of the mouse foregut at E9–9.5 and evaginates into the splanchnic mesenchyme as the primordial trachea and two main stem

bronchi are formed. The tracheal and bronchial stalks extend, the latter forming the main bronchi, a process completed by approximately E10.5 in the mouse. Most vertebrate lungs display right-left asymmetry. For example, there are three main lobes on the right and two on the left in

**FIG. 73.2.** Maturation of the pulmonary mesenchyme — vasculogenesis. Generally considered a relatively undifferentiated group of mesodermally derived cells, the pulmonary mesenchyme provides the progenitor cells for multiple cell types, including pulmonary and bronchial blood vessels (arteries, capillaries, veins, and lymphatics), smooth muscle cells surrounding the bronchial tubules, as well as stromal cells supporting peripheral lung saccules and distal regions of the conducting airways. Panel **A** demonstrates the early formation of vascular networks surrounding the lung tubules at E12.5 in the mouse, which are marked by the expression of  $\beta$ -galactosidase in pulmonary vascular cells under control of the *flk-lacZ* construct. Panel **B** demonstrates the organization of pulmonary vessels and stroma in relationship to bronchial and saccular structures in the late prenatal period of mouse lung development, demonstrating the complexity of organogenesis near the time of birth.

humans. A number of transcription factors have been implicated in the establishment of *situs inversus* in the mouse embryo (Raya and Belmonte, 2006).

FGF-10 from the mesenchyme (Deacon *et al.*, 1998), FGF-R2 in the endoderm (De Moerlooze *et al.*, 2000), SHH/GLI 2,3 (Litington *et al.*, 1998; Pepicelli *et al.*, 1998), and retinoic acid receptors (RARs) (Mendelsohn *et al.*, 1994) play important roles during this early period of tracheal-pulmonary morphogenesis. While TTF-1 is required for formation of the peripheral lung and for complete separation of esophagus and trachea, the upper trachea, main bronchi are formed in mice lacking TTF-1 (Kimura *et al.*, 1996), FGF-10 (Deacon *et al.*, 1998), or FGF-R2IIIb (De Moerlooze *et al.*, 2000). There is considerable redundancy in RAR receptor function. Deletion of multiple RARs caused severe tracheal and lung malformations, including lung hypoplasia and agenesis (Mendelsohn *et al.*, 1994). Lung formation is also dependent on sonic hedgehog (SHH), produced by the endodermally derived cells, that is secreted, activating Ptch/Smo/Gli on the pulmonary mesenchyme (Pepicelli *et al.*, 1998). *Shh*<sup>-/-</sup> mice have tracheoesophageal fistula and simple cystlike lung sacs that fail to branch. As exemplified by the SHH and FGF pathways, multiple signaling centers are likely to control autocrine-paracrine signaling among and between endodermal and mesenchymally derived cells during formation of the lung that drive transcriptional processes influencing gene expression and cell behavior.

### Reciprocal Interactions Between Epithelial and Mesenchymal Cells

The development of the pulmonary mesenchyme, from which blood vessels and supportive tissue are formed, is carefully synchronized with that of the endodermally derived lung tubules. Stereotypic branching and budding occur as the bronchial and bronchiolar tubules form between approximately E11 and E16 in the mouse and are accompanied by the development of an extensive blood supply from both bronchial and pulmonary circulations. During this period, pulmonary blood vessels are produced by vasculogenesis and angiogenesis. Blood vessels coalesce and extend along the lung tubules to produce pulmonary arteries, veins, and lymphatics. Smooth muscle cells also differentiate, proliferate, and migrate along the bronchial tubules. Nerves are observed along vascular structures, innervating primarily the conducting regions of the lung. Cartilage appears along the ventral region of the trachea and bronchi in a precisely spaced manner. The lung tubules gradually taper along the cephalocaudal axis. Precartilaginous regions of the airway are well established by E11–E12 in the mouse, being marked by expression of Sox9 in precartilaginous tracheal-bronchial mesenchyme. Deletion or mutation in a number of transcription factors and signaling molecules, including SHH (Miller *et al.*, 2004), Sox9 (Mori-Akiyama *et al.*, 2003), RARs (Mendelsohn *et al.*, 1994), FGF signaling (Davis *et al.*, 1992), and FGF-18 (Whitsett *et al.*,

**FIG. 73.3.** Airway differentiation during the canalicular-saccular period. Structures and cell types differ along the cephalocaudal axis of the lung. A complex pseudostratified epithelium lines the larger cartilaginous, conducting airways. In many species, submucosal glands are located between the cartilaginous rings and in the submucosal layers. The epithelium consists primarily of ciliated, nonciliated, goblet, neuroendocrine, and basal cells (**A**). The bronchi and bronchioles are lined primarily by a simple columnar epithelium consisting of ciliated and nonciliated epithelial cells as well as a rare subset of neuroendocrine cells that are found as isolated cells or in clusters termed neuroendocrine bodies (NEBs) (**B**). The bronchoalveolar ducts are lined by cuboidal cells, leading to the saccules and alveoli that make up the peripheral gas exchange region of the lung (**C**).

2002), disrupt tracheal cartilage formation in the developing mouse lung. Thus by E16, the general structure of the lung is well established along multiple axes, providing the scaffolding on which region-specific differentiation of various pulmonary epithelial cells begins.

Lung formation is highly dependent on reciprocal interactions between numerous cell types of both endodermal and mesenchymal origins. Removal of splanchnic mesenchyme that surrounds the developing lung buds arrests cell proliferation and branching morphogenesis (Wessells, 1970). The proliferation and differentiation of endodermal cells is strongly influenced by the underlying mesenchyme. For example, peripheral mesenchyme from the tips of lung buds to tracheal endoderm results in ectopic budding, branching, and peripheral lung specification of the upper airway (trachea), demonstrating remarkable plasticity of cell type during formation of the lung (Deterding and Shannon, 1995). It is likely that these interactions are controlled by cell-cell as well as paracrine and autocrine signals among various pulmonary cells. Ligands and receptors mediating these complex events are incompletely known. As seen in early embryonic patterning of the foregut, FGF signaling also plays an important role during branching morphogenesis. Evidence from gene targeting in the mouse suggests the important roles of FGF-10 (Deacon *et al.*, 1998), FGF-18 (Usui *et al.*, 2004), and FGF-9 (Colvin *et al.*, 2001), each playing an important and distinct role in lung formation. FGF-10 is sufficient to enhance cell migration, budding, and branching of the embryonic lung (Bellusci *et al.*, 1997). Conversely, the underlying endodermal cells synthesize and secrete a number of molecules critical for survival, proliferation, and differentiation of the pulmonary mesenchyme, including sonic hedgehog (SHH), vascular endothelial growth factors (VEGFs), and bone morphogenic proteins (BMPs).

### Epithelial Cell Differentiation During the Canalicular-Saccular Period

While respiratory epithelial cells lining the lung tubules consist of a relatively undifferentiated columnar-cuboidal cell layer in the embryonic period, a number of morphologically and biochemically distinct cell types become apparent during the canalicular-saccular period in the latter third of gestation. Epithelial surfaces of the larger cartilaginous airways are generally lined by a pseudostratified columnar epithelium consisting of basal, ciliated, goblet, Clara (non-ciliated secretory cells), intermediate cells, and others. Many species, including the human, have large numbers of tracheal-bronchial submucosal glands, which also consist of numerous cell types. In most species, smaller airways, including bronchioles and respiratory acinar ducts, are lined by a single columnar or cuboidal epithelium, which consists primarily of ciliated and nonciliated secretory cells, as well as pulmonary neuroendocrine cells (PNECs), the

latter a relatively rare cell type that expresses various neuropeptides. In the alveoli, peripheral lung epithelial cells become cuboidal (type II) or squamous (type I) as the peripheral saccules form. The numbers and characteristics of cells lining the respiratory tract vary along both dorsal–ventral and cephalocaudal axes and change dynamically during lung development. Numbers and differentiation of various epithelial cell types also vary during injury and repair in the postnatal period. The cellular and molecular mechanisms underlying the differentiation and maintenance of these diverse cell populations are being actively studied at the present, providing a conceptual framework useful in exploring lung regeneration and repair.

### Sacculation and Alveolarization

As if the processes of lung formation during branching morphogenesis were not complex enough, dramatic changes also occur in the saccular-alveolar period of lung development, as the structural transitions required for perinatal lung function occur. During this period, the distal fluid-filled lung saccules dilate. Epithelial cells proliferate and differentiate and the lung mesenchyme thins, as pulmonary blood capillaries come into close association with the walls of the lung saccules. At birth, the lungs expand, lung liquid is cleared, pulmonary blood flow increases, and surfactant is secreted into the alveoli to reduce surface tension as required for expansion. During the perinatal and postnatal period of lung growth, until maturity, the alveoli proliferate and septate, increasing the surface area available for gas exchange. The sacculation and alveolarization process is strongly influenced by stretch, requiring space for growth and expansion. Pressure from the amniotic fluid and production of lung liquid regulate growth of the peripheral lung. Various growth factors and hormones, including FGFs, EGF, PDGF, TGF- $\beta$ , VEGFA, retinoids, and glucocorticoids, influence processes in the saccular-alveolar period of lung morphogenesis.

## IV. ENDOGENOUS PROGENITOR CELLS PLAY CRITICAL ROLES IN REPAIR OF THE RESPIRATORY EPITHELIUM AFTER BIRTH

After birth, the respiratory tract provides a remarkably large surface area that comes in direct contact with pathogens, particles, and toxicants present in inhaled air. In spite of the constant exposure to millions of particles each day, the respiratory tract is generally maintained in a sterile condition and is able to respond rapidly and robustly to various pulmonary injuries and infections. Repair of the respiratory epithelium depends primarily on endogenous cells lining the distinct regions of conducting and peripheral airways. Since respiration must be maintained at all times for survival, cellular responses mediating repair are initiated immediately following injury, resulting in rapid repair of the epithelium while maintaining alveolar-capillary permeabil-

ity and pulmonary homeostasis. Failure of repair, as seen in overwhelming infections, sepsis, or inhalation (e.g., following burns or smoke inhalation), causes loss of alveolar capillary integrity, often resulting in respiratory failure, termed *adult respiratory distress syndrome* (ARDS). Since the lung adapts to many pulmonary infections via both innate and acquired immune responses, the respiratory tract initiates remarkable protective and proliferative responses. Complex innate and acquired immune systems mediate the clearance of infected cells and pathogens. Since injury and infection often involve extensive regions of the lung, maintenance of epithelial barrier function must be maintained during the process of clearance of apoptotic or necrotic cells. It is therefore not surprising that the lung is capable of robust proliferative responses, which can be initiated throughout the tissue. In general, cell proliferation occurs at very low rates in the mature lung, in sharp contrast to findings in some organs, like the gastrointestinal tract, in which ongoing, rapid turnover of cells occurs. While the mature respiratory epithelium does not undergo rapid turnover (Breuer *et al.*, 1990), the respiratory epithelium responds rapidly to acute injury, and many cell types are capable of reentering the cell cycle during the repair process.

In conducting airways, there is strong evidence that basal cells and nonciliated epithelial cells proliferate rapidly and play important roles in the repair of the respiratory epithelium after various types of injury. *In vitro* and *in vivo* experiments have demonstrated the ability of basal cells, Clara cells, or other secretory cells, including epithelial cells in the bronchio-alveolar–duct junctions, to proliferate and differentiate into other respiratory epithelial cell types (Plopper *et al.*, 1992; Van Winkle *et al.*, 1995, 1999; Reynolds *et al.*, 2000a, 2000b; Hong *et al.*, 2001, 2004; Giangreco *et al.*, 2002; Lawson *et al.*, 2002). Progenitor cells, whether stem cells or transient amplifier cells, proliferate and migrate during the repair of the injured airways. These progenitor cells are present in varying numbers in distinct cell niches along the conducting airways. Repair of alveolar cells is initiated by the proliferation of type II epithelial cells and their subsequent differentiation into alveolar type I cells (Evans *et al.*, 1975, 1976).

### Models for Study of Lung Repair

Evidence from multiple experimental models used to study lung repair support the concept that endogenous cells provide the major, if not sole, cellular substrates for the repair of respiratory epithelium following acute injury (Plopper *et al.*, 1992; Bongso *et al.*, 1994; Reynolds *et al.*, 2000a, 2000b; Hong *et al.*, 2001, 2004; Giangreco *et al.*, 2002; Lawson *et al.*, 2002; Schoch *et al.*, 2004; Park *et al.*, 2006). A number of experimental models have been used to elucidate the cellular mechanisms involved in lung repair, including exposure to toxicants, infectious agents, and immunological challenges. Repair of the conducting airway epithelium has been studied using a variety of chemical and

toxicant challenges selectively to injure specific cell types. Nonciliated cells (Clara cells) lining conducting airways of the mouse can be selectively killed with the toxicant naphthalene, which is metabolized to highly toxic metabolites, a process controlled by the expression of cytochrome P450, which is highly expressed in nonciliated respiratory epithelial cells (Plopper *et al.*, 1992; Van Winkle *et al.*, 1995, 1999; Reynolds *et al.*, 2000a, 2000b; Hong *et al.*, 2001, 2004; Giangreco *et al.*, 2002). Metabolites of naphthalene cause rapid and extensive injury of nonciliated cells in conducting airways. Basal cells play an important role during repair of the pseudostratified epithelium in the upper airways after naphthalene exposure (Bongso *et al.*, 1994; Borthwick *et al.*, 2001; Hong *et al.*, 2004). In the bronchioles, repair is initiated within hours after injury by the transdifferentiation and squamous metaplasia of ciliated or other toxicant-resistant cells in smaller conducting airways (Plopper *et al.*, 1992; Lawson *et al.*, 2002; Park *et al.*, 2006). These cells migrate and redifferentiate to contribute to the normal, heterogeneous cellularity of the airways within several days following injury. In the mouse, toxicant resistant or variant Clara cells and cells located near neuroendocrine bodies and in the bronchio-alveolar-duct region proliferate most actively following naphthalene exposure (Hong *et al.*, 2001; Kim *et al.*, 2005). Epithelial repair is accompanied by increased expression of a number of genes that are normally expressed during lung morphogenesis, including Foxa1, Foxa2, TTF-1, Sox2, Sox17, and Foxj1 (Park *et al.*, 2006). Thus, squamous metaplasia and transdifferentiation of existing airway epithelia play an important role in maintaining and repairing the respiratory epithelium after injury. The precise nature and state of differentiation of cells undergoing proliferation are not known with clarity, although a number of experiments support the concept that basal cells and nonciliated cells, as well as cells in distinct cell niches, are capable of proliferation, migration, and differentiation to restore the respiratory epithelium. Whether these cells are tissue stem cells or simply represent diverse populations of rapidly amplifying cells is unclear at present. Various toxicants have been used to study lung injury, including exposure to sulfur dioxide, ozone, detergents, and nitric oxide, which in general support the concept that both basal cells and nonciliated respiratory epithelial cells are the major source of progenitors that repair conducting airways after injury (Evans *et al.*, 1986).

Various *in vitro* model systems using isolated cells, xenografts, and tracheal-epithelial cells cultured at an air-liquid interface demonstrate the ability of various lung cells to proliferate and differentiate into multiple cell types. For example, purified basal cells and/or Clara cells can reform the complex epithelia consisting of numerous cell types (Bongso *et al.*, 1994; Schoch *et al.*, 2004). *In vitro* labeling of clones with retroviral vectors demonstrates the varying clonal potential for progenitor cells as the respiratory epithelium is regenerated during the reepithelialization of tra-

cheal grafts (Engelhardt *et al.*, 1991). Ciliated, nonciliated epithelial, and goblet cells are produced from these progenitors. In the peripheral lung, exposure to hyperoxia (80–95%) causes acute cell injury, inducing proliferation in subsets of epithelial cells. Alveolar type I cells are most susceptible to oxygen injury. Alveolar repair is initiated by proliferation of alveolar type II epithelial cells, which occurs two to three days following the injury. Subsets of these cells then differentiate into type I cells to complete the repair (Evans *et al.*, 1975).

### Evidence for Specialized Stem Cell Niches

The identity and properties of putative stem cells in the lung remain of considerable interest and are subject of active investigation. At present, specific markers and characteristics of the proposed stem cells have not been identified. Nevertheless, there is considerable evidence for pulmonary cells with stem cell characteristics. Tissue stem cells capable of continued self-renewal and proliferation have been proposed to play a role in the repair of multiple organs and tissues, including the lung. Stem cells are generally considered to represent a rare subset of nonproliferating cells that are normally maintained in an undifferentiated state. Such cells may be identified by prolonged retention of BrdU or <sup>3</sup>H thymidine, which is incorporated into DNA during recurrent injury and proliferation of cells, termed *label-retaining cells* (LRCs). LRCs turn over slowly, are capable of self-renewal, and are able to provide progenitor cells that proliferate and differentiate. A number of experiments provide evidence for LRCs in specified niches within the respiratory tract (Reynolds *et al.*, 2000a, 2000b; Borthwick *et al.*, 2001; Engelhardt, 2001). LRCs were identified in the lung of mice exposed to naphthalene and after repeated exposure to detergent or SO<sub>2</sub>, where they were identified in relatively restricted sites along conducting airways. LRCs were enriched in the necks of submucosal glands and in tracheal-bronchial folds in noncartilaginous regions of the conducting airways. After injury, these cells proliferated and migrated to repair the respiratory epithelium. The sites enriched in these LRCs are perhaps strategically located to minimize their direct injury from toxicants, or infection. Distinct surfaces of various cell types lining the respiratory epithelium may also determine their susceptibility to injury, toxicants, or infection. For example, the diverse cell surfaces present on various cells may influence attachment and/or uptake of pulmonary pathogens by the respiratory epithelium. Subsets of cells located near neuroepithelial bodies and those located near branch points of conducting airways were associated with repair following severe injury (Hong *et al.*, 2001). Cells located in bronchoalveolar ducts may represent another subset of cells with unique proliferative and differentiation capacities (Giangreco *et al.*, 2002; Kim *et al.*, 2005). Thus the lung is repaired primarily by the proliferation of endogenous progenitor cells, whose numbers and locations vary along the cephalocaudal

axis of the airways. The cellular and molecular mechanisms involved in proliferation and redifferentiation is of considerable relevance in efforts to apply lung progenitor cells to tissue engineering.

### Lessons from Postpneumonectomy Regeneration

The remarkable capacity of the mammalian lung to regenerate following ipsilateral pneumonectomy provides evidence for the potential of tissue reengineering of the lung. This phenomenon contrasts sharply with the loss of lung function associated with many chronic pulmonary disorders, in which severe tissue loss and remodeling permanently impair lung function. In most mammals, ipsilateral pneumonectomy initiates rapid cell proliferation capable of substantially restoring lung functions and reserve capacity, a phenomenon that is well known clinically and experimentally. Many cellular components of the lung are involved in the regeneration process. Regrowth is strongly influenced by tissue caused by expansion of the remaining lung following removal of tissue and, to a lesser extent, by hypoxemia and endocrine factors. Regeneration is species and age dependent, the less mature lung being capable of more robust responses. In many animal models, growth of both airway and alveolar epithelium can occur in a balanced fashion, the growth of pulmonary vessels accompanying that of the respiratory tubules and maintaining ventilation/perfusion ratios. Under some experimental conditions, epithelial expansion occurs in a nonsynchronous fashion with that of the vascular system, resulting in limited improvement in gas exchange. As in other models of lung repair, proliferation and remodeling are mediated by the proliferation of endogenous pulmonary cells, and there is no evidence that exogenous or marrow-derived progenitor cells contribute substantially or biologically to the growth process. A number of peptides and hormones, including epidermal growth factor, platelet-derived growth factor, fibroblast growth factors, and retinoic acid, influence the repair process following pneumonectomy (Hsia, 2004). Although retinoids can enhance lung repair in experimental emphysema (Massaro and Massaro, 1997, 2000), the administration of retinoic acid alone does not enhance lung regeneration in dogs (Yan *et al.*, 2005). The ability of the mature lung to undergo remarkable compensatory growth, leading to enhanced pulmonary function, is a remarkable observation that provides a foundation for further investigation of tissue engineering of the lung.

## V. EVIDENCE FOR NONPULMONARY STEM CELLS IN THE LUNG

A number of controversial experiments provides support for the ability of marrow-derived or mesenchymal progenitor cells to contribute significantly to repair of the lung. Several studies support the concept that bone marrow

stromal cells or mesenchymal-derived progenitor cells can migrate into various organs, where they express features of endogenous cells, including respiratory epithelial, myocardial, and gastrointestinal cells (Krause *et al.*, 2001; Kotton *et al.*, 2005). While engraftment and differentiation of cells in the lung rarely occur following bone marrow transplantation in normal mice, lung injury enhances the migration of bone marrow-derived cells into the lung. However, recent studies suggest that some of the engrafted cells may represent the fusion of bone marrow-derived cells with endogenous cells rather than the reprogramming and redifferentiation of the cells (Terada *et al.*, 2002; Chang *et al.*, 2005; Kotton *et al.*, 2005). Artifactual colocalization of cell-specific markers with other cell-labeling markers was demonstrated after bone marrow transplantation, further complicating interpretations of previous findings. The use of careful optical sectioning/imaging systems to discriminate colocalization from overlying or superimposing images was recommended (Kotton *et al.*, 2005). Thus, at the present time there is little evidence that bone marrow-derived cells play biologically relevant roles in lung repair. Nevertheless, the potential for the application of multipotent progenitor cells for use in cell replacement or tissue repair remains intriguing and merits further investigation.

The potential utility of embryonic stem cells for tissue regeneration is being actively explored for therapies of many diseases and multiple organs. Embryonic stem cells exhibit varied abilities to differentiate along distinct cell lineages, which can be further influenced by growth in selective media, by the addition of growth factors or extracellular matrix components, and/or by coculture with other cell types. Recent studies demonstrate that embryonic stem cells can differentiate into cells with characteristics of respiratory epithelial cells expressing lung-specific markers, including pro SP-C or Clara cell secretory protein (CCSP) (Coraux *et al.*, 2005; Van Vranken *et al.*, 2005). Coculture of embryonic lung mesenchyme with ES cells demonstrated the ability of the mesenchymal cells to enhance differentiation toward respiratory epithelial cell types (Van Vranken *et al.*, 2005). Nuclear extracts obtained from MLE-12 cells (an SV40 large T-antigen immortalized cell line) enhanced pulmonary selective differentiation of embryonic stem cells *in vitro* (Qin *et al.*, 2005). SV40 large T-antigen ES cells differentiate into multiple cell types, including those that express a variety of endodermal cell markers, when transplanted under renal or testicular capsules. Culture of ES cells at an air-liquid interface produced a complex, highly differentiated epithelium, with cell types characteristic of conducting airways, including ciliated, basal, and secretory cells (Coraux *et al.*, 2005). Taken together, ES cells may provide a source of cells that can be cultured under various conditions to enhance their differentiation into respiratory epithelial cell types. ES cells will be useful in identifying factors and processes regulating growth, differentiation,

and specification of respiratory epithelial cells and will enable the study of their interactions with other pulmonary cell types. The utility of ES cells for regenerating pulmonary tissues that would be of therapeutic value remains to be explored.

## VI. MODELS FOR STUDY OF LUNG REGENERATION *IN VITRO*

While no single system has been developed for regeneration of functional lung tissue capable of engraftment into the lung, a number of model systems have been developed that allow the study of various aspects of the processes that will be required for lung regeneration. The remarkable complexity of the lung and its requirement for bronchial pulmonary arterial and lymphatic circulations as well as its connection to the conducting airways and the cardiovascular system present a considerable engineering hurdle. Various pulmonary cell types can be isolated and grown under conditions that retain their capacity to reorganize into lunglike structures *in vitro*. However, pulmonary cells cannot be readily infused or explanted into airways or into the pulmonary circulation to induce formation of functional tissue. Nevertheless, useful model systems for the study of lung regeneration have been developed for *in vitro* and *in vivo* studies. Various epithelial cell types, including basal, ciliated, and nonciliated airway cells, as well as alveolar type I and type II cells, can be substantially purified by differential protease treatments, cell sorting, differential attachment, and/or density gradient separation strategies. In general, respiratory epithelial cells rapidly lose their differentiated cell characteristics unless placed on specialized matrices or grown as organoids in which multiple cell types are cocultured. Various epithelial cell types can be immortalized from using transforming viruses or after expression of transforming genes in transgenic mice (Wikenheiser *et al.*, 1993). Such cells have been highly useful for the study of lung cell biology.

Respiratory epithelial cells differentiate in response to various culture conditions. Highly differentiated lung cells maintaining some of the features of lung parenchyma can be produced by coculture of dissociated fetal lung cells on collagen sponges (Gelfoam) (Douglas and Teel, 1976) or on other biomatrices, including Matrigel, a collagen-glycosaminoglycan rich matrix. Cell polarity, epithelial-mesenchymal cell interactions, and epithelial cell differentiation can be maintained under these conditions. Fetal lung has been explanted and maintained in culture for several days, during which epithelial cells undergo differentiation. Highly differentiated cell cultures of conducting airway epithelial cells have been produced by culture of

mature respiratory epithelial cells on denuded trachea (Liu *et al.*, 1994). Tracheal grafts can be seeded with lung cells and then implanted and cultured under the skin of nude mice for prolonged periods of time. A highly differentiated pseudostratified respiratory epithelium consisting of multiple respiratory cell types forms under these conditions. Similarly, a complex epithelium can be generated by culturing isolated conducting airway cells on various biomatrices at an air-liquid interface (Coraux *et al.*, 2005; Vaughan *et al.*, 2006). However, in these models, growth and differentiation of lung epithelial cells occur without connection to blood vessels. The long-term viability of lung explanted tissue has been demonstrated in a xenograft model, in which explanted fetal lung tissue develops a vascular system that connects to the host circulation (Vu *et al.*, 2003). Both fetal lung explants, and embryonic stem cells transplanted under the testicular or renal capsules of SCID mice develop blood vessels derived by vasculogenesis from the explanted tissue, which connect with the host vascular system (Schwarz *et al.*, 2000; Vu *et al.*, 2003). Thus, a number of useful model systems, including those with isolated cells, ES cells, xenografts, and fetal lung explants, have been developed that are useful in exploring the complex biology underlying lung regeneration and repair. Fruitful lines of investigation support the concept that pulmonary cells can be isolated and cultured under conditions that was not in the growth of highly differentiated cells with many of the features of normal lung.

## VII. SUMMARY AND CONCLUSIONS

Disorders of the lung contribute substantially to morbidity and mortality throughout life. Lung malformations, genetic disorders affecting the lung, and diseases related to prematurity and other perinatal lung diseases represent the most common cause of illness in the perinatal period. Likewise, acute lung disease and chronic lung disease are encountered throughout postnatal life. Thus, the ability to provide lung tissue to enhance lung function would have diverse applications in medicine in the future. Knowledge regarding the fundamental principles underlying lung formation will provide the conceptual framework required to enhance normal lung repair and allow regeneration of lung tissue for treatment of inherited and acquired lung diseases. Because of its complexity, tissue engineering of the lung capable of enhancing respiration represents a high hurdle in the field of regenerative medicine. The study of lung formation, repair, and tissue engineering will likely provide knowledge regarding the cellular and molecular processes that allow for future cell- and tissue-based therapies for the treatment of lung disease.

### I. INTRODUCTION

Repair or regeneration of defective lung cells or tissue would be of huge therapeutic potential. Cellular sources for the regeneration of lung tissue *in vivo* or lung-tissue engineering *in vitro* include endogenous pulmonary epithelial stem cells, extrapulmonary circulating stem cells, and embryonic stem cells. This chapter discusses the progress that has been made toward creating regenerative-medicine approaches to the treatment of lung injury and disease.

There is no doubt that a readily available means to repair, replace, or regenerate human lung tissue would have an enormous impact on health care. A huge variety of lung diseases exist, and most are debilitating and widespread and present a significant biomedical problem. Chronic obstructive pulmonary disease (COPD, or smoker's lung) alone affected more than 52 million individuals around the world in 1994, with approximately 16.2 million of these living in the United States, and is predicted to become the third-leading cause of death worldwide by 2020 (Pauwels *et al.*, 2001). In addition to the human suffering, the attendant financial burden is enormous: in 1993, \$14.7 billion were spent on treatment of COPD, with the overall direct and indirect costs estimated at more than \$30 billion (Sullivan *et al.*, 2000). Despite the significant burden lung diseases place on society, research funding has historically been disproportionately low, and the biological processes underlying many lung diseases remain poorly understood.

The ultimate aim of any regenerative-medicine strategy is to restore normal cellular architecture and function where tissues have been compromised by injury or disease. The lung is a particularly difficult target for any reparative or regenerative strategy for three main reasons: it has a highly complex structure, there is a wide range of cellular diversity and the pulmonary epithelium shows slow cell turnover rates. However, during recent years there has been a series of scientific advances leading toward targeted lung repair and/or regeneration. For example, our understanding of fetal lung morphogenesis has increased, and previously unknown regenerative pathways have been identified in the adult lung. Some of the most pivotal advances have been made in the area of stem cell biology, which has become big news in medical research since the mid-1990s. As the basis of natural pathways for tissue maintenance and regeneration, stem cells represent a key target for mediating repair *in vivo*. The targeted activation of endogenous pools of airway epithelial cells with the properties of stem cells could exploit existing repair mechanisms and augment the lung's innate regenerative capability. Implantation of pulmonary-epithelium or even pulmonary-tissue constructs produced *in vitro* has yet to be achieved but progress is being made in this direction too. In addition to the direct clinical benefits of such laboratory-created lung epithelium and/or tissue, they could be used as *in vitro* models of human lung development and disease for further investigation and

manipulation and for drug discovery and toxicological testing.

The degree to which the lung can repair itself through the proliferation and differentiation of intrinsic stem cells is discussed in Chapter 73. In this chapter, we concentrate on the basic research being done with a view to repairing damaged lung and eventual engineering of the gas exchange component of the lung.

## II. LUNG STRUCTURE

In brief, the mammalian lung comprises branching airways that become narrower at each divergence until they form the small alveolar sacs at the distal ends that act as the gas exchange unit. There are about 300 million alveoli in the adult lung, providing the surface area in the order of 60–80 square meters that is needed for human respiration. Replicating such a structure in the laboratory is a truly daunting prospect for the tissue engineer. The pulmonary tree contains distinct anatomical regions, each lined by a confluent layer of different types of epithelial cells that forms the interface with the air space. Underlying the epithelium is the vasculature lined by endothelial cells, which, like the epithelium, form a continuum, in this case running from the main pulmonary artery, through capillaries, to the pulmonary vein and on to the left atrium. In between the epithelial and endothelial layers lies the pulmonary interstitium, which comprises a range of connective tissue cell types providing a scaffold for cell layers within the lung. The following summarizes the structure of these three main components of the lung.

### Epithelium

The proximal airways, the trachea and major bronchi, are lined by pseudostratified epithelium containing ciliated and mucous secretory (or goblet) cells on the luminal surface. Neuroendocrine cells first appear around eight weeks of gestation in human lung and are relatively frequent during development, where they play a major role in airway growth and development and form in the adult around 1% of the pulmonary epithelium (Lauwreyns and Cokelaere, 1973; Cutz and Orange, 1977). The lining of the smaller airways also includes ciliated epithelial cells, but, rather than goblet cells, the bronchioles possess the different, cuboidal, nonciliated Clara cells. The alveoli are lined by two epithelial phenotypes: the flattened squamous (type I) and the cuboidal (type II) pneumocytes. The type I pneumocyte is the cell type across which gas exchange occurs, and it is characteristically thin, with cytoplasmic extensions, a morphology that presents as little a barrier as possible to the diffusion of oxygen while maintaining the integrity of the alveolar wall. Type II pneumocytes are critical for maintaining alveolar homeostasis, clearing the alveolar air space of edema and secreting pulmonary surfactant that lowers surface tension and prevents airway collapse.

### Endothelium

The vasculature of the lung is different from that of the systemic circulation in a variety of ways: the vessels are of low resistance, blood in arteries is deoxygenated whereas that in veins is oxygenated, and specialized structural modifications of the alveolar capillaries promote gas diffusion. Throughout the pulmonary vasculature, the endothelial cells are continuous, bathed on one side by blood and on the other by interstitial fluid, and, unlike the epithelium, they share most characteristics, although there are some differences related to the function of each segment. For example, arterial endothelium is composed of relatively thick, elongated cells with numerous cytoplasmic organelles. Venous endothelial cells are thinner and polygonal and have fewer organelles, while those of the alveolar capillaries have an avascular zone, the basal lamina of which fuses with that of type I pneumocytes to form the air–blood barrier.

### Interstitium

The interstitium, the space interposed between the air-space epithelium, the vascular endothelium and the pleural mesothelium, is the remains of the splanchnopleuric mesenchymal bed into which the airway tubes and blood vessels grew during lung morphogenesis. The cells of the interstitium are a spectrum, from smooth muscle to fibroblasts. Stops in between include myofibroblasts and pericytes, which are the particular myofibroblasts associated with the alveolar capillaries. Immune cells, in the form of macrophages and lymphocytes, mainly T-cells, are present in the interstitial fluid. A web of elastin and collagen fibers, interwoven with fibronectin fibrils and proteoglycan molecules, permeates the interstitial space and forms the matrix that supports the structural integrity of the lung while allowing its plastic deformation during respiration. The epithelial and endothelial basal laminae are considered the outer borders of the pulmonary interstitium.

## III. CELL SOURCES FOR LUNG REPAIR AND LUNG-TISSUE ENGINEERING

Primary cells, derived from body fluid, tissue outgrowth, or disaggregation, can be used for tissue repair and engineering but present problems of access, limited life span and failure to maintain phenotype *in vitro*. Primary cells have been used successfully, however, in the construction of *in vitro* models of lung. Stem cells, in contrast, can be isolated relatively easily from embryonic, fetal, or adult tissue, can self-renew (by definition) and can be encouraged to form a required cell phenotype, although all stem cell types are not equivalent because the range of cell types to which they can differentiate varies according to origin. For regenerative-medicine purposes, stem cells could provide a virtually inexhaustible cell source. Large-scale production of regenerative-medicine products, including cell therapies

and engineered tissue constructs, could be envisaged if undifferentiated stem cells were expanded in culture and driven in batches to differentiate into different therapeutic cell types. Consequently, current research is focused on developing means to expand stem cells, to promote their efficient differentiation to required lineages, and to purify and manipulate the resulting cells into a form suitable for implantation (see Polak and Bishop, 2006, for review). For each potential target cell type or tissue, the initial step in developing a tissue-engineering strategy is the selection of the most appropriate stem cell on which to base it. As mentioned earlier, the structural complexity and cellular heterogeneity of the lung make the study of lung-specific stem cell biology difficult, so the isolation of sufficient numbers of pulmonary stem cells for potential therapeutic applications is simply unrealistic at this time. For this reason, attempts have been made to produce pulmonary epithelium from extrapulmonary stem cell types, which can be isolated and grown in greater numbers.

### Circulating Stem Cells

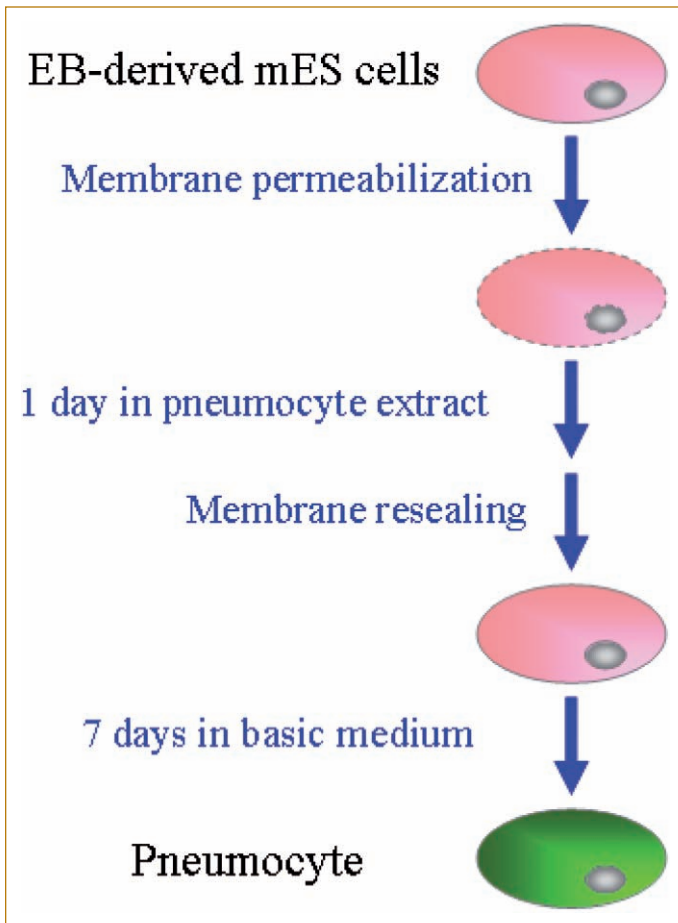

One possible source of stem cells for use in lung epithelial repair could be the circulation. Our understanding of the regeneration of many organs has been revised in recent years with the discovery that various tissues can be repaired by stem cells recruited from the circulation. Adult bone marrow has long been known to contain stem cells that can give rise to hematopoietic and mesenchymal cell lineages (Pittenger *et al.*, 1999). However, these stem cells can differentiate not only toward a variety of mesenchymal cell types, such as adipocytes (Pittenger *et al.*, 1999), osteocytes (Prockop 1997; Perreira *et al.*, 1998), myocytes (Ferrari *et al.*, 1998), and cardiomyocytes (Orlic *et al.*, 2001), but also toward ectoderm, e.g., neurons (Mezey *et al.*, 2000) and endoderm, e.g., hepatocytes (Petersen *et al.*, 1999; Alison *et al.*, 2000; Lagasse *et al.*, 2000; Theise *et al.*, 2000), and renal parenchymal cells (Poulsom *et al.*, 2001). These observations have been taken to suggest that there is a subpopulation of stem cells in adult bone marrow that retains pluripotency throughout development and can act as a universal repair pathway. Consistent with this, multipotent adult progenitor cells (MAPCs) have been described in murine bone marrow that can differentiate *in vitro* at the single-cell level to all three germ layers (Jiang *et al.*, 2002). Although the mechanism by which bone marrow-derived stem cells are recruited to repair tissue is not known, engraftment has been reported to be enhanced by tissue injury (Ferrari *et al.*, 1998; Kotton *et al.*, 2001; Okamoto *et al.*, 2002; Theise *et al.*, 2002; Ortiz *et al.*, 2003; Abedi *et al.*, 2004).

For the lung, there is some controversy as to whether stem cells are recruited from the circulation to repair the epithelium and, if so, whether or not this occurs by fusion with cells *in situ*. A variety of cell-tracing experiments has been carried out, using labeled or marker-mismatched cells derived from bone marrow fractions in murine models.

Marrow-derived cells were identified in most cases in the pulmonary epithelium of recipient mice, and the rate of engraftment was generally found to be improved in areas of overt lung damage (Kotton *et al.*, 2001; Theise *et al.*, 2002; Ortiz *et al.*, 2003; Krause *et al.*, 2001; Grove *et al.*, 2002; Harris *et al.*, 2004; Ishizawa *et al.*, 2004; Mattsson *et al.*, 2004; Yamada *et al.*, 2004; Beckett *et al.*, 2005; Loi *et al.*, 2006). In one of these studies, bone marrow-derived pulmonary epithelium was seen 11 months after cell implantation, suggesting that this is a mechanism for effecting long-term repair (Grove *et al.*, 2002). Apparent engraftment and trans-differentiation could be explained by fusion of bone marrow stem cells with endogenous somatic cells. This has been demonstrated *in vitro* (Terada *et al.*, 2002; Ying *et al.*, 2002; Alvarez-Delado *et al.*, 2003) and also *in vivo* in cells known to form heterokaryons in certain pathologies, such as hepatocytes and cardiomyocytes (Alvarez-Delado *et al.*, 2003; Vassilopoulos *et al.*, 2003; Deb *et al.*, 2003). Tests with pulmonary epithelium have given mixed results, with fusion with bone marrow stem cells being clearly demonstrated *in vitro* (Spees *et al.*, 2003) but not seen *in vivo* (Grove *et al.*, 2002; Alvarez-Delado *et al.*, 2003; Harris *et al.*, 2004). However, more recently, the results of all these studies have been questioned because of their reliance on colocalization of the bone marrow-specific label with pulmonary epithelial markers by microscopy. Two studies in animal models have been published arguing that these findings are actually a consequence of separate overlapping cells or autofluorescence, not true colocalization of markers, as originally suggested (Chang *et al.*, 2005; Kotton *et al.*, 2005).

There is another aspect of bone marrow stem cell engraftment in lung that concerns the discovery of lung-specific side population (SP) cells within pulmonary tissue. SP cells, identified by their unique flow cytometry profile when stained with the DNA dye Hoechst 33342, were originally shown in the bone marrow as being highly enriched for hematopoietic stem cell activity (Goodell *et al.*, 1996). But recently, nonhematopoietic SP cells have been identified that seem to act as tissue-specific stem cells (Alvi *et al.*, 2002; Wulf *et al.*, 2003; Poliakova *et al.*, 2004). SP cells, with the characteristics of airway epithelium and mesenchyme, have since been isolated from proximal and distal lung (Summer *et al.*, 2003, 2004; Giangreco *et al.*, 2004). Originally thought to represent another tissue-specific stem cell population, the most recent data show that lung-specific SP cells have a bone marrow origin, although they are phenotypically distinct from bone marrow SP cells (Summer *et al.*, 2004). It is not known whether these cells colonize the lung during development only or are continually renewed throughout life by the bone marrow.

So far, investigation of human lung either has found no engraftment of bone marrow cells within the pulmonary epithelium or has shown that it occurs only infrequently (Kubit *et al.*, 1994; Bittmann *et al.*, 2001; Kleeberger *et al.*, 2003; Surratt *et al.*, 2003; Albera *et al.*, 2005; Zander *et al.*,

**FIG. 74.1.** Diagrammatic representation of cell extract-based reprogramming of embryonic stem cells to derive type II pneumocytes as described in Qin *et al.* (2005). EB = embryoid body; mES = murine embryonic stem.

2005). Unfortunately, these studies have been fraught with technical problems due to their reliance on the questionable colocalization of histological markers and the lack of appropriate human lung tissue samples of adequate quality. Nevertheless, if it is true that stem cells can be recruited by damaged pulmonary epithelium to effect repair, then there could be major clinical implications. As a precedent, the observation that bone marrow cells engraft in murine and human heart was rapidly translated to the clinic, where administration of autologous bone marrow, directly to the cardiac wall or via the vasculature, is being used to treat myocardial infarction and heart failure (see Wollert and Drexler, 2005, for review). It has also been reported recently that delivery of a specific fraction of stem cells in mobilized peripheral blood, which shows early markers for cells of all germ layers, can be used to reduce liver insufficiency in human patients (Gordon *et al.*, 2006). The complexity of the lung may make similar therapy more difficult to achieve for respiratory diseases, but it may at least be possible to up-

regulate the natural repair process in a similar manner. If exogenous bone marrow or circulating stem cells could be delivered to the lung for repair, this could also provide a novel means for gene therapy. Isolated stem cells from the bone marrow or the circulation may be a source for the engineering of lung constructs, if they can be purified and expanded in sufficient numbers.

### Embryonic Stem Cells

Embryonic stem cells (ESC) are particularly suited to tissue-engineering research, in view of their relative availability, known provenance, pluripotency and proliferative capacity (see Rippon and Bishop, 2004, for review). For derivation of lung cells, preliminary findings established the possibility of deriving alveolar airway epithelium, specifically type II pneumocytes, from murine ESC by supplementation of the culture medium with factors that maintain differentiated characteristics in primary lung epithelial cell cultures (Ali *et al.*, 2002; Rippon *et al.*, 2004). These ESC-derived cells express surfactant proteins, have an ultrastructure comparable to that of primary type II pneumocytes (i.e., they have microvilli and lamellar bodies) and differentiate *in vitro* on plastic to type I pneumocytes. The original protocol has recently been refined and found to give rise to progenitor cells thought to be representative of those present in the early branching lung, around E10–E11 of murine development, which differentiate to form Clara cells and type I and type II pneumocytes (Rippon *et al.*, 2006).

It has proven difficult to produce yields of lung epithelial cells from ESC of more than a few percent by the manipulation of cell culture medium alone, an observation made for other endodermal cell lineages. Subsequently, other means have been tested to drive the formation of pulmonary epithelium from ESC. For example, it has been reported that combining medium supplementation with cell culture at an air–liquid interface can induce the formation of fully differentiated tracheobronchial airway epithelium from murine ESC (Coraux *et al.*, 2005). Alternatively, a method originally used to convert fibroblasts into T-cells using T-cell extracts (Håklien *et al.*, 2002) has been adapted and applied to murine ESC. This method involved permeabilizing stem cells and exposing them for one hour to crude lysates of a type II pneumocyte cell line. Following membrane resealing and culture in unsupplemented medium, the cells differentiated to type II pneumocytes with an efficiency of approximately 10%, well in excess of that observed with most other methods (Qin *et al.*, 2005) (Fig. 74.1).

In view of the critical role that underlying mesenchymal cells play in regulating lung epithelial differentiation *in vivo*, the inductive power of fetal lung mesenchyme on ESC has been investigated. Early differentiating embryoid bodies were wrapped in microdissected lung mesenchyme taken from E11.5 mouse embryos. After only five days, mesenchyme and ESC had coalesced and small channels had

formed that were lined by cells expressing markers of alveolar epithelium (Van Vranken *et al.*, 2005). A similar approach has recently shown that the inductive properties of murine lung mesenchyme persist for only a short developmental window around embryonic day 11.5, the stage at which distal lung epithelial differentiation is initiated *in vivo* (Denham *et al.*, 2006). This approach may prove too limited to provide lung tissue for implantation, but it could provide a system for modeling lung development *in vitro*.

The basic research with murine cells obviously needs transfer to human cells before any firm steps can be made toward clinical applications. For ESC, this exercise is really just beginning, for human lines were isolated only in 1998 (Thomson *et al.*, 1998), and it is only within the last several years that they have become readily available to laboratories lacking the highly specialized expertise and facilities to isolate their own. Recently, type II pneumocytes were successfully differentiated from human ESC (Samadikucharsaraei *et al.*, 2006) (Fig. 74.2), the first crucial step in the development of ESC-based treatments for lung disease. Whether ESC-derived pulmonary epithelial cells or engineered tissue will be used in the clinic remains to be seen because there are safety issues, principally regarding the possibility of accidental implantation of undifferentiated cells, that have yet to be addressed. In the meantime, there is no doubt that, at the very least, these cells have a range of indirect therapeutic applications, such as in disease modeling, drug discovery and toxicological screening.

#### IV. LUNG-TISSUE CONSTRUCTS

Lung tissue has been constructed for *in vitro* use. For example, EpiAirway™ (www.Matteck.com) comprises normal, nonimmortalized human tracheal and bronchial epithelial cells cultured to form a pseudostratified structure that resembles pulmonary epithelial tissue. These constructs have been used in drug delivery research and toxicological testing. Similar models have been made of bronchus, specifically for the *in vitro* study of the mechanisms underlying asthma (Chakir *et al.*, 2001; Paquette *et al.*, 2003, 2004). For these, bronchial fibroblasts were seeded into a collagen gel and bronchial epithelial cells were grown on the surface. There have been attempts to engineer trachea for implantation (Kojima and Vacanti, 2004), and the first successful human case was recently reported (Omori *et al.*, 2005). In addition to direct implantation of an engineered construct, there has been early work on the engineering of trachea by aerosol delivery of cells (Roberts *et al.*, 2005). Although not yet tested in an animal model, an atomizer has been developed that successfully sprays mammalian chondrocytes and tracheal epithelial cells, with more than 70% viability and no effect on growth rate. An interesting feature of this system was the placing of the cells in a mixture of saline and the polymer Pluronic F-127, which is liquid at room temperature but gels in the body. This means that, on

**FIG. 74.2.** (A) Human embryonic stem cell-derived type II pneumocytes identified by their immunoreactivity for the specific marker surfactant protein C (surfactant protein C immunoreactivity = green; propidium iodide nuclear counterstain = red). (B) Transmission electron micrograph of a human embryonic stem cell-derived type II pneumocyte showing the typical ultrastructure with lamellar bodies and microvilli.

instillation, the aerosol will gel in contact with the airway surface, thereby promoting adherence and engraftment of the cells.

The generation in the laboratory of the complex gas exchange component of the lung for human implantation, however, remains an elusive goal for tissue engineers. Pneumocytes attach fairly well to a range of polymer or bioactive scaffolds, particularly if an appropriate extracellular matrix protein is coated on the scaffold surface, e.g., laminin (Tan *et al.*, 2002) (Fig. 74.3). Attempts to create distal lung tissue can be traced back as far as 1976, when dispersed rat fetal pneumocytes grown on a collagen sponge reaggregated

**FIG. 74.3.** (A) Scanning electron micrograph showing a single murine type II pneumocyte growing on the surface of Bioglass™. (B) A similar cell to that shown in (A) following coating of the surface of Bioglass™ with the extracellular matrix protein laminin. The cell shows increased spreading and contact with the scaffold surface.

around a lumen to form something that mimicked alveoli (Douglas and Teel, 1976; Douglas *et al.*, 1976a, 1976b). These alveolar-like structures, which formed within two days of culture and could be maintained for up to six weeks, were found to be composed mainly of type II pneumocytes, which were functional in that they secreted surfactant (Douglas *et al.*, 1983). Similar apparent reconstitution of alveolar structures *in vitro* has been reported for neonatal (Saito *et al.*, 1985) and adult rat lung cells grown on collagen gel (Sugihara *et al.*, 1993) or basement membrane (Shannon *et al.*, 1987; Kalina *et al.*, 1993) and for fetal rabbit lung cells grown on basement membrane (Blau *et al.*, 1988; Chinoy *et al.*, 1994). More recent developments in this area include the growth of dissociated rat lung cells on a collagen-glycosaminoglycan (GAG) tissue-engineering scaffold (Chen *et al.*, 2005). Not only did alveolar-like structures form, but the construct exhibited cell-mediated contraction, and smooth muscle actin was found in some of the cells in the scaffold, suggesting the formation of elastic units, as happens *in vivo*. The work also indicates the

potential usefulness in lung-tissue engineering of a scaffold, collagen-GAG, that is already well established in tissue engineering, e.g., for skin (Yannas *et al.*, 1989). Implantation of such a scaffold, seeded with cells possibly of a stem cell origin, as described earlier, might form the basis of a future engineering strategy. Another group reports the growth of mixed embryonic murine lung cells (epithelium, endothelium, and mesenchyme) in 3D on Matrigel and synthetic polymers (poly(lactic-co-glycolic) acid (PLGA), poly(L-lactic) acid (PLLA) formed into either foams or nanofibrous scaffolds (Mondrinos *et al.*, 2006). When grown on the hydrogel, it was possible to up-regulate the branching and sacculation of the resulting alveolar-like tissue by adding bFGF, FGF-7/10 to the culture medium. An exciting recent development has been the engineering of alveolar tissue by growing isolated lung progenitor cells on synthetic polymers (Cortiella *et al.*, 2006).

Artificial lungs, in the form of ECMOs (extracorporeal membrane oxygenators) or ECLS (life support systems), are being used in the clinic, but these are relatively inefficient and entirely mechanical at present. These systems are used mainly in cardiopulmonary bypass during heart surgery, but they are also used, to a lesser extent, to support patients in respiratory failure. Work is in progress to improve these machines, for example by increasing efficiency and/or making them intrathoracic, with a view to creating systems designed specifically for providing extended respiratory support (see Federspel and Henchir, 2004, for review). One means being investigated is to make the devices into bio-hybrids. A major step on the long, rocky road to making lung tissue for implantation could be the incorporation of epithelial and/or endothelial cells in extracorporeal gas exchange devices. For this latter possibility, the researchers at Imperial College London are collaborating with a company, Novalung™ (<http://www.novalung.com>), to try to increase the efficiency and life span of their interventional lung-assist device that is already in the clinic by incorporating stem cell-derived epithelium to make a biohybrid system.

## V. CONCLUSIONS

Tissue engineering promises to revolutionize our approach to the treatment of injury and disease. Lung disease is extremely prevalent worldwide, yet many lung diseases remain effectively incurable without a transplant, and the numbers of donor organs continues to dwindle. The latest research suggests that controlled and targeted lung repair could be effected by at least three methods: activating the body's existing repair pathways and stem cell pools, implanting healthy cells or tissue grown from stem cells in the laboratory or a combination of elements of both strategies. Exciting advances have been made in both areas in recent years, but the time frame for getting any of these approaches into the clinic remains unknown.

### I. INTRODUCTION

The field of epithelial stem cells is progressing rapidly, largely because of technical advances in molecular and cellular biology. Many astute observations over the last century led to predictions about epithelial stem cells that only recently have been definitively addressed through new techniques. Originally, putative epithelial stem cells were identified in the hair follicle bulge as quiescent “label-retaining cells.” The study of these cells was hindered until the identification of bulge cell molecular markers, such as CD34 expression and K15 promoter activity. This allowed for the isolation and characterization of bulge cells from mouse follicles. Bulge cells possess stem cell characteristics, including multipotency, high proliferative potential, and their cardinal feature of quiescence. Lineage analysis demonstrated that all epithelial layers within the adult follicle and hair originated from bulge cells. Bulge cells only contribute to the interfollicular epidermis during wound healing. But after isolation, when combined with neonatal dermal cells, they regenerate new hair follicles, epidermis, and sebaceous glands. Bulge cells maintain their stem cell characteristics after propagation *in vitro*, so ultimately they may be useful

for tissue-engineering applications. The isolation, characterization, and manipulation of stem cells in the skin holds promise for their future use in clinical applications for treatment of a variety of skin disorders, including hair loss (alopecia), wounds, pigmentary disorders, and skin aging. Here, we review the evolution of current thinking on cutaneous epithelial stem cells and delineate future challenges for applying our knowledge to reap clinical benefits.

The epidermis consists of multiple cell types and layers. The outermost layer, called the *stratum corneum*, is composed of dead corneocytes, which adhere tightly to each other to form a hydrophobic barrier that protects us from the environment and prevents water loss. The innermost layer at the base of the epidermis generates new cells that migrate to the surface while terminally differentiating and eventually forming the stratum corneum. In addition to keratinocytes, which produce intermediate filament proteins called *keratins* and constitute the majority of the cells, the epidermis houses melanocytes, which produce pigment, and Langerhans cells, which present antigen.

The epidermal surface is interrupted by orifices arising from adnexal structures, such as the hair follicle and sweat

glands. The epidermis continues down into these structures, and cells from hair follicles and sweat ducts can move out and repopulate the epidermis after wounding. The adnexal structures possess a greater degree of tissue complexity than the epidermis. For example, in contrast to the stratified squamous epithelium of the epidermis, the hair follicle consists of at least eight different concentric layers of epithelia, which undergo degeneration and regeneration with each hair follicle cycle.

## II. WHAT ARE EPITHELIAL STEM CELLS?

Because self-renewing tissues, such as the epidermis and the hair follicle, continuously generate new cells to replenish the dead corneocytes and hairs, which are sloughed into the environment, their homeostasis is thought to be dependent on epithelial stem cells. Therefore, perhaps the simplest definition of an epithelial stem cell is based on lineage: *A stem cell is the cell of origin for terminally differentiated cells in adult tissues.* For example, tracing the lineage of a corneocyte or hair cell back to its ultimate source in adult skin leads to a stem cell. However, because the tools required to perform lineage analysis have not been available until recently, investigators have principally adopted definitions from the hematopoietic system. In particular, stem cells were felt to be self-renewing, multipotent, and clonogenic, similar to stem cells in the hematopoietic system, which can regenerate all of the blood lineages from one cell. In contrast to hematopoietic stem cells, cutaneous epithelial stem cell biologists also relied heavily on quiescence as a major stem cell characteristic. This can be attributed to the pioneering work of Bickenbach and Mackenzie (1984), who devised “label-retaining cell” methods for detecting quiescent cells in the epidermis, and of Morris and Potten, who showed that these cells retained carcinogens and possessed proliferative characteristics of stem cells (reviewed in Morris, 2000).

## III. LOCALIZATION OF EPITHELIAL STEM CELLS

With respect to the epidermis (which in this chapter refers to the interfollicular epidermis), we know that cells are generated through proliferation that occurs only in the basal layer; therefore, stem cells must be located there. Within the basal layer, however, keratinocytes display heterogeneous proliferative characteristics. In mouse skin, individual basal cells divide less frequently than the surrounding cells. The slower-cycling central cell and more rapidly proliferating surrounding cells constitute approximately 10 basal cells and are roughly organized into a hexagonal unit, which lies beneath a single keratinocyte (reviewed in Kaur, 2006). Based on these proliferative and morphological characteristics, the term *epidermal proliferative unit* (EPU) was coined to describe this architecture (Morris, 2000; Kaur, 2006). Without the benefit of direct

lineage analysis, it was assumed that the central cell within the EPU generates the rapidly proliferating cells, termed *transient* or *transit amplifying* (TA) cells, which move laterally and then differentiate and move upward. Thus, within the epidermis, the main source of cells, i.e., the stem cells, responsible for continual epidermal renewal appear to reside in the center of the EPU, and testing of this concept in unmanipulated epidermis on the back of the mouse supports this view (Ito *et al.*, 2005).

Similar to the epidermis, the hair follicle generates a terminally differentiated keratinized end product, the hair shaft, which is eventually shed. Tracing back a hair shaft cell to its origin in adult skin is not straightforward. In contrast to epidermis, the follicle undergoes cyclical regeneration and has a more complicated proliferative profile and architecture, with at least eight different epithelial lineages (Fig. 75.1). Hair is formed by rapidly proliferating matrix keratinocytes in the bulb located at the base of the growing (anagen) follicle. The duration of anagen varies drastically between hairs of differing lengths. For example, mouse hair and human eyebrow hair follicles stay in anagen for only two to four weeks, while scalp follicles can remain in anagen for many years. Nevertheless, matrix cells eventually stop proliferating, and hair growth ceases at catagen when the lower follicle regresses to reach a stage of rest (telogen). After telogen, the lower hair-producing portion of the follicle regenerates, marking the new anagen phase.

Because the lower portion of the follicle cyclically regenerates, hair follicle stem cells were thought to govern this growth. Historically, hair follicle stem cells were assumed to reside exclusively in the secondary germ (Fig. 75.2), which is located at the base of the telogen hair follicle. It was felt that the secondary germ moved downward to the hair bulb during anagen and provided new cells for production of the hair. At the end of anagen, the secondary germ was thought to move upward with the dermal papilla during catagen to come to rest at the base of the telogen follicle. This scenario of stem cell movement during follicle cycling was brought into question when a population of long-lived presumptive stem cells was identified using label-retaining cell methods in an area of the follicle surrounding the telogen club hair and not in the hair bulb (Cotsarelis *et al.*, 1990). That the presumptive stem cells localized to a previously defined area called the *bulge* was not appreciated until I read a description of the human embryonic follicle by Hermann Pinkus (1958):

This *bulge*, often the most conspicuous detail of the young germ, is as large as the bulb. . . . The function of the bulge is obscure. While it serves as the point of insertion of the arrector muscle later in life, it develops much earlier than the muscle and the latter seems to originate quite independently in the skin near the sebaceous gland, and in many instances streaks by the bulge before approaching the lower follicle below it. Unna (1876) named the bulge area of the adult follicle the *hair bed* (Haarbett), believing that the club hair became implanted there and derived

**FIG. 75.1.** Hair cycle and anatomy. The hair follicle cycle consists of stages of rest (telogen), hair growth (anagen), follicle regression (catagen), and hair shedding (exogen). The entire lower epithelial structure is formed during anagen and regresses during catagen. The transient portion of the follicle consists of matrix cells in the bulb that generate seven different cell lineages, three in the hair shaft and four in the inner root sheath (IRS).

additional growth from it. Stöhr gave it the neutral name “Wulst” (bulge or swelling). Some texts state that this is an area of marked proliferative activity, but no mitotic figures were observed in the bulge even if other parts of the follicle contained them. Whatever its function, the bulge marks the lower end of the “permanent follicle” later in life. Everything below it is expendable during the hair change [cycle].

This remarkable description, based purely on morphological observations, portended the characterization of the bulge cells in both human and mouse follicles as an area containing quiescent cells important for hair follicle cycling (Cotsarelis *et al.*, 1990; Lyle *et al.*, 1998; Morris *et al.*, 2004). In the mouse pelage follicle, the area analogous to the human bulge becomes morphologically apparent in the postnatal period during the first telogen stage at the site of arrector pili muscle attachment. The shape of the bulge in the mouse follicle results from displacement of the outer root sheath (ORS) by the club hair. In the human follicle, the bulge appears as a true thickening of the ORS, but it generally becomes much less apparent with age (Fig. 75.3).

The lack of markers for bulge cells hindered the study of this area. To date, probably the best (most specific) marker for mouse hair follicle bulge cells is CD34 expression, as first

defined by Trempus *et al.* (2003). CD34, which interestingly is also a hematopoietic stem cell marker in the human but not the mouse, highlights the bulge cells specifically within the cutaneous epithelium. Although it is also expressed by cells in the dermis, it is a cell surface protein, and antibodies recognizing CD34 can be used to collect viable bulge cells by fluorescent activated cell sorting. This allows for the isolation and molecular characterization of the bulge cells.

Keratin 15 expression in human bulge cells was first described by Lyle *et al.* (1998) (Fig. 75.3). K15 mRNA and protein are reliably expressed at high levels in the bulge, but lower levels of expression can be present in the basal layers of the lower follicle outer root sheath and the epidermis. Thus the use of K15 expression as the sole criterion for defining a bulge cell is not advisable. However, a K15 promoter used for generation of transgenic mice possesses a pattern of activity restricted to the bulge in the adult mouse (Liu *et al.*, 2003). This proved to be a powerful tool for studying bulge cells and is discussed later.

A salient feature of the bulge cells is their quiescence. In both adult mouse and human skin grafted to immunodeficient mice, the administration of nucleoside analogs, such as tritiated thymidine or bromodeoxyuridine, which are taken up by cells in S-phase, does not result in labeling of

**FIG. 75.2.** Location of hair follicle stem cells: two models. In one view, the “secondary germ cells,” named for their similarity to primary germ cells present during development, were thought to contain the stem cells for the follicle. It was thought that these cells migrated from the base of the telogen follicle to the bulb during anagen onset and then migrated back up during catagen. To date, no direct evidence (e.g., label-retaining cell studies or lineage analysis) has been presented that any epithelial cells in the bulb survive during catagen. The secondary germ cells found at the base of the telogen follicle appear to arise from the lowermost portion of the bulge at the end of catagen (Ito *et al.*, 2004). Based on morphology, the telogen secondary germ generates the new hair and IRS, although this needs to be addressed experimentally. The origin and fate of the matrix keratinocytes in the bulb, which possess an undifferentiated phenotype, is an area worthy of exploration. It is not known whether bulge cells migrate down the follicle during anagen to supply the matrix cells continuously with new cells or whether the matrix cells self-renew throughout anagen.

the bulge cells, except at anagen onset (Ito *et al.*, 2002; Ito *et al.*, 2004). Once labeled as either neonates or during anagen onset, when stem cells are proliferating, bulge cells can remain labeled for 14 months in the mouse and at least four months (the longest period examined) in the human (Lyle *et al.*, 1998). This prolonged quiescence is remarkable, given that the surrounding cells proliferate at a much higher rate, which suggests that bulge cells persist for the lifetime of the organism.

Once the bulge cells were identified as presumptive epithelial stem cells, based on their ability to retain label, it was necessary to evaluate whether these cells possessed other expected characteristics important for stem cells. In particular, did they exhibit a high proliferative potential? Were they multipotent, generating all epithelial cell types within the follicle as well as epidermis and sebaceous gland? Did they have a molecular signature of stemness shared with other stem cell populations? These questions were important not only from a biological perspective, but also from a therapeutic one. A better understanding of the role of bulge cells in renewal of the epithelium should provide insights into wound healing, gene therapy, aging, and carcinogenesis.

#### IV. IN VITRO ASSESSMENT OF PROLIFERATIVE POTENTIAL

Proliferative capability can be assayed *in vitro* by examining the clonogenicity of individual keratinocytes through serial passage. Approximately 5% of adult epidermal basal cells possess a “holoclone” phenotype characterized by high reproductive capacity and low level of terminal differentiation. These cells are thought to represent stem cells (Barrandon and Green, 1987). Colony-forming efficiency (CFE; colonies per number of cells plated) serves as another indicator of proliferative capability and is thought to correlate with the number of stem cells in a tissue (Kobayashi *et al.*, 1993). These kinds of analyses revealed that the epidermis possesses three major types of cells, based on their proliferative capacity *in vitro*. Terminally differentiated cells have no proliferative capacity, TA cells have a limited capacity (forming abortive small colonies), and epidermal progenitor cells have clonogenic capacity (Jones *et al.*, 1995). For the epidermis, the number of colony-forming units is likely representative of the stem cell population, although direct proof, through lineage analysis, that all central cells within the EPU are holoclones is lacking.

**FIG. 75.3.** The bulge is a prominent structure in fetal skin (A), but generally is not morphologically distinct in the adult (B). Immunostaining for keratin 15 in scalp preferentially detects bulge cells (C). apm, arrector pili muscle.

Similar analyses have also been applied to the hair follicle epithelium, with mixed and sometimes contradictory results. In rat vibrissae (whisker follicles), CFE analysis localizes the large majority (>95%) of holoclones to the hair follicle bulge (Kobayashi *et al.*, 1993). However, in human hair follicles, CFE was reported greatest outside of the bulge region, in the lower outer root sheath (Rochat *et al.*, 1994). This was surprising, since this portion of the follicle undergoes degeneration during catagen, and these data are not in line with *in vivo*, label-retaining studies that localize LRC to the human hair follicle bulge (Lyle *et al.*, 1998). Possible explanations for the culture results are that current culture conditions actually support propagation of progenitor cells in addition to hair follicle stem cells or that culturing keratinocytes leads to “reprogramming” events that overestimate the number of true stem cells within a tissue.

Some of the discrepancies are explained by studies on vibrissa follicles, which show that the stage of the follicle at the time of isolation influences how well cells grow in culture (Oshima *et al.*, 2001). Since human hair follicles are not synchronized in their growth relative to one another, and since the anagen stage in human follicles lasts for many years, each isolated anagen follicle that was analyzed for CFE may have yielded very different results (Rochat *et al.*, 1994). For example, a follicle that has been in anagen for only one

month might produce a greater number of colonies from the bulge than one in anagen for six years, which may have more colonies from lower portions of the follicle.

Other types of *in vitro* studies based on epithelial outgrowths from explanted follicles have also produced conflicting results. Whole follicle explant cultures give rise to epithelial growths from the ORS (Yang *et al.*, 1993; Moll, 1996). In one study, the outgrowths were seen in the area believed to represent the bulge of human hair follicles (Yang *et al.*, 1993). In another, many outgrowths were seen in the upper central ORS, which was believed to be lower than the bulge but which likely includes the lower portion of what is the bulge (Moll, 1996). Again, these differences may be related to the heterogeneity of anagen in human follicles. More recently, however, Roh *et al.* (2005) decreased the influence of the hair follicle cycle by concentrating on telogen follicles, which possess a well-defined bulge area. They demonstrated major differences between bulge cells and matrix cells *in vitro*. The bulge cells possessed a higher proliferative potential than the matrix cells, while the matrix cells possessed a very mobile phenotype, demonstrated by time-lapse photography (matrix keratinocytes migrated 0.7  $\mu\text{m}/\text{min}$ , compared to 0.1  $\mu\text{m}/\text{min}$  for bulge cells). These data support the idea that bulb matrix keratinocytes are TA cells and possess a finite proliferative potential. This concept

was originally proposed as an explanation for why anagen follicles eventually enter catagen (Cotsarelis *et al.*, 1990), although this needs further testing.

Recent data using CFE and holoclone analysis remain mixed, although most of the data support the idea that the bulge cells possess a high proliferative potential. Isolated bulge cells grown on feeder cells *in vitro* formed more numerous colonies than nonbulge keratinocytes (Trempey *et al.*, 2003). Morris showed that isolated bulge cells formed larger and more numerous colonies (Morris *et al.*, 2004). Blanpain *et al.* (2004) reported that the large majority of holoclones originate from the bulge in the adult mouse, while basal epidermis did not form any holoclones, although both of these populations had similar colony-forming efficiency. Given that similar culture conditions were used for all three studies, these findings may reflect the inherent variability and difficulty in interpreting *in vitro* proliferation studies (Joseph and Morrison, 2005).

## V. MULTIPOTENT BULGE CELLS?

If the stem cells of the hair follicle are located in the bulge, then these cells should give rise to all of the lower hair follicle epithelial cell layers. Early evidence supporting the concept that bulge cells generate the lower follicle includes proliferation studies showing that bulge cells proliferate preferentially at anagen onset (Wilson *et al.*, 1994; Ito *et al.*, 2004). More convincing evidence suggesting that the lower follicle originates from bulge cells came from *in vivo* labeling studies and transplantation studies. Taylor used a double-labeling technique to trace the progeny of bulge cells in intact pelage follicles (Taylor *et al.*, 2000). Faint labeling in a speckled pattern was observed in some cells of the lower follicle, suggesting that these cells had indeed originated in the bulge. Similarly, Tumber *et al.* (2004) used persistence of GFP label as an indication that lower epithelial cells were progeny of the bulge cells. Neither study provided convincing evidence that all hair matrix keratinocytes in the bulb originated from bulge cells, and both suffered from an inability to mark bulge cells and their progeny permanently. Oshima *et al.* (2001) took a different approach and transplanted bulge regions from vibrissa follicles isolated by dissection from ROSA26 mice into non-ROSA follicles that were then grafted under the kidney capsule of an immunocompromised mouse. ROSA26 mice express *lacZ* under the control of the ubiquitous ROSA promoter, so the fate of the transplanted cells could be followed. After several weeks, they found labeled cells in the lower follicle, indicating that bulge cells or their progeny had migrated down the vibrissa follicle. At later time points, some follicles expressed *lacZ* in all epithelial cell layers of the lower follicle, suggesting that bulge cells do generate all of the cells of the lower follicle. These elegant studies were limited because of the unclear starting cell population, the manipulation performed during grafting, and the use of vibrissa follicles, which are markedly different than other mouse and human follicles.

More definitive evidence for bulge cell multipotency *in vivo* was reported using the K15 promoter to target these cells with an inducible Cre (CrePR1) construct (Morris *et al.*, 2004). CrePR1 is a fusion protein consisting of Cre-recombinase and a truncated progesterone receptor that binds the progesterone antagonist RU486 (Berton *et al.*, 2000). In *K15-CrePR1* transgenic mice, CrePR1 remains inactive in the cytoplasm of the K15-positive cells, except during RU486 treatment, which permits CrePR1 to enter the nucleus and catalyze recombination. We crossed the *K15-CrePR1* mice with *R26R* reporter mice (Berton *et al.*, 2000) that express *LacZ* under the control of a ubiquitous promoter after Cre-mediated removal of an inactivating sequence. Transient treatment of adult *K15-CrePR1;R26R* mice with RU486 results in permanent expression of *LacZ* in the bulge cells and in all progeny of the labeled bulge cells. From this approach, it is clear that cells originating in the bulge generated all epithelial cell types in the lower hair follicle.

Although these studies convincingly showed that the bulge cells as a whole gave rise to the lower follicle, none of these approaches addressed the question of how many stem cells participate in the formation of the new anagen follicle or at what point bulge cells or their progeny are committed to specific lineages (Kamimura *et al.*, 1997; Ghazizadeh and Taichman, 2001; Kopan *et al.*, 2002). Several studies have examined lineage within the follicle using reconstitution assays in which isolated keratinocytes are combined with neonatal dermal cells and grafted onto a nude mouse skin (Weinberg *et al.*, 1993). The mixture then forms hair follicles. By using a combination of keratinocytes labeled with a retrovirus encoding alkaline phosphatase plus nonlabeled keratinocytes for the epithelial component of the assay and then examining the proportion of labeled cells within the follicle, an indication of the number of clones within a follicle can be inferred (Kamimura *et al.*, 1997; Topley *et al.*, 1999). Dotto and Cotsarelis (2005) suggested that the majority of reconstituted follicles arose from three different clone types: one each for the ORS, the IRS, and the hair shaft. Other combinations were also present, including some follicles with partial labeling within one of the layers. Only rarely were entire follicles labeled, indicating that they may have arisen from single cells. The limitations of the reconstitution studies include the manipulation of the cells required for the reconstitution of the follicle, which likely mimics a wound-healing environment that is not normal; the resulting follicles lack normal orientation and often grow at right angles to each other — this limits the ability to accurately orient the follicles in tissue sections and makes analysis of clones difficult; the growth cycle of the follicles is not synchronized, making the evaluation of the hair cycle almost impossible. This especially limits evaluation of the bulge, which is most evident during telogen. Lastly, silencing of the reporter construct or its inadequate expression in follicle subpopulations may complicate matters as well.

Kopan, using chimeric mice, presented evidence for approximately four different clones within a follicle, but each with the ability to generate all epithelial cell types within the follicle (Kopan *et al.*, 2002). These chimeric studies were also limited by manipulation during embryogenesis. Related studies by the same group looked at X-inactivation in adult mice, and the findings support the concept that hair follicle stem cells are multipotent. But these studies were limited by the use of vibrissa follicles analyzed during the neonatal time period. Another recent study, examining Cre mice exhibiting recombination events of low frequency within their cells, also recognized several different types of clones responsible for different follicle layers (Legue and Nicolas, 2005). None of these three studies assessed clones within the bulge during telogen, so the question of how many and which bulge cells participate in hair follicle formation at anagen onset remains unanswered.

Ultimately, formal lineage analysis will be needed to elucidate the exact contribution of individual bulge cells to the different lineages within the follicle. Questions remaining include: At what point, if any, are stem cells set aside during development? When are hair follicle lineages established? That is, are individual bulge cells committed to a specific lineage, or is each bulge cell multipotent? How many bulge cells are required to generate a new lower anagen follicle, and is the number different based on the size and type of follicle? The answers may be important for designing cell-based treatments for alopecia (Stenn and Cotsarelis, 2005).

## VI. PLASTICITY OF BULGE CELLS?

Intriguing results suggest that cells isolated from the mouse hair follicle bulge area have the potential to differentiate into multiple different nonepithelial tissues, including Schwann cells and neurons (Amoh *et al.*, 2005). These cells were isolated from nestin-eGFP-transgenic mice (Li *et al.*, 2003). Nestin is a neural stem cell marker. The exact origin of the nestin positive cells and whether they represent a single or mixed population of cells need to be addressed. Because nestin was not differentially expressed in mouse or human bulge cells (Morris *et al.*, 1986; Tumber *et al.*, 2004; Ohyama *et al.*, 2006), it is unlikely that these cells represent keratinocytes. However, regardless of their origin, nestin-positive cells from the skin possess remarkable regenerative capabilities when used in a nerve injury model (Amoh *et al.*, 2005). Similar *in vitro* plasticity findings using cells isolated from human follicles were also reported (Yu *et al.*, 2006); thus, the follicle could serve as a source of cells for a variety of tissue-engineering applications in the future.

## VII. BULGE CELLS: THE ULTIMATE CUTANEOUS EPITHELIAL STEM CELLS?

In addition to the role of the bulge cells in the formation of the hair follicle at anagen onset is a question of whether

bulge cells are necessary for the homeostasis of the epidermis and sebaceous gland. One view is that bulge cells continuously provide progeny that repopulate these tissues (Lavker and Sun, 2000; Taylor *et al.*, 2000). If true, then ablation of the bulge should lead to failure of epidermal renewal. Recent experiments show that loss of bulge cells does not lead to loss of the epidermis, suggesting that the epidermis possesses stem cells capable of renewing themselves for long periods. Other studies have shown long-term persistence of clones within the epidermis. These studies utilized reconstitution assays (Kamimura *et al.*, 1997; Ghazizadeh and Taichman, 2001). Some evidence was provided that hair follicle-derived cells did move into the epidermis, especially adjacent to the hair follicle, but it was not clear that these cells were derived from the bulge. Morris *et al.* (2004) and Tumber *et al.* (2004) did find that bulge cells can move into the epidermis, but this was not systematically studied using lineage analysis. Recent work in which isolated bulge keratinocytes were injected into neonatal mice and then followed showed that bulge cells contributed to the epidermis after engrafting, but eventually no cells arising from the injected cells were found in the epidermis, implying lack of movement of bulge cells to the epidermis (Claudinot *et al.*, 2005).

Studies addressing directly the questions of whether and when bulge cell progeny migrate to the epidermis have recently been accomplished. Using the K15CrePR;R26R-transgenic mouse, bulge cells were labeled in three-week-old mice (Morris *et al.*, 2004). Mice were followed for six months to determine the movement of bulge-derived cells into the epidermis. At the end of the experiment there was no evidence that bulge-derived cells had migrated to epidermis. Thus, under homeostatic conditions, the epidermis alone is responsible for its continual renewal. These findings are important for gene therapy since it will be important to target stem cells within the epidermis to correct genetic disorders such as epidermolysis bullosa (a congenital blistering disorder).

## VIII. ROLE OF BULGE CELLS IN WOUND HEALING

The contribution of the hair follicle to healing of the epidermis following wounding has been appreciated for decades by investigators working with mice and rabbits (Argyris, 1976). Clinicians are also well aware that keratinocytes emerge from the follicle to repopulate wounds. However, the role of the bulge cells in wound healing has only recently been characterized.

Bulge cell progeny migrate to the epidermis after different types of wounding. Using the K15CrePR;R26R-transgenic mouse, bulge cells were labeled in adult mice (Ito *et al.*, 2005). Excisional wounding with a 4-mm (punch) trephine resulted in the migration of bulge cell progeny into the healing epidermis. At least 25% of the newly formed

epidermis originated from the bulge cells. Bulge cells were also stimulated to move into the epidermis following incisional wounds and after tape stripping, indicating that bulge cell activation plays a role in replenishing lost cells from the epidermis after wounding. Surprisingly, however, despite the presence of bulge-derived cells in the basal layer of the reepithelialized epidermis, the majority of the bulge-derived cells did not persist in the regenerated epidermis. This suggests that bulge cells and epidermal stem cells are intrinsically different, in that epidermal-derived cells seem better suited for establishing long-term epidermal proliferative units.

## IX. ROLE OF BULGE CELLS IN TUMORIGENESIS

Since epithelial stem cells are thought to have a life span at least as long as that of the organism, they are thought to be susceptible to multiple genetic “hits” that cumulatively may result in tumor formation. A great deal of evidence in the mouse system points to hair follicles and stem cells as the origin of many skin tumors (Morris, 2000). Keratinocyte stem cells appear to be the target of cutaneous carcinogens, and, since they are the slowest-cycling cells, hair follicle stem cells also retain carcinogens for extended periods and are thus more susceptible to tumor promotion (Morris, 2000).

Since human basal cell carcinomas (BCCs) are slowly growing tumors, composed of poorly differentiated cells with the ability to differentiate into various adnexal structures, it has been suggested that the cell of origin is a multipotent stem cell that is slowly cycling and has a high proliferative potential (Cotsarelis *et al.*, 1990). There is considerable evidence that BCCs may arise from stem cells within the hair follicle (Hutchin *et al.*, 2005). BCCs have been shown to express bcl-2 (Verhaegh *et al.*, 1997), a marker of the permanent portion of the hair follicle, including the bulge (Stenn *et al.*, 1994). Furthermore, the overexpression of sonic hedgehog (SHH) in mouse epidermis causes BCC-like tumors from invaginating hair follicles but has little effect on interfollicular epidermis (Oro *et al.*, 1997), again suggesting a follicular origin for BCCs. The SHH signaling pathway, including *ptc*, is active in hair follicle morphogenesis during fetal development (Millar, 2002).

Because trichoepitheliomas (TEs), a benign type of hair follicle tumor, and BCCs have a similar clinical and histological appearance and may develop concurrently in some patients, it has been proposed that these tumors arise from a common precursor cell type within the hair follicle (Headington, 1976). Biochemically, both TEs and BCCs express cytokeratins 5, 6, 14, 17, and 19 (Schirren *et al.*, 1997), a profile found in the infundibular outer root sheath cells of the normal hair follicle, in fetal germ cells, and in the fetal hair follicle bulge. In addition, in one study,

13 of 13 TEs and about one-third of BCCs expressed K15, suggesting they originate from bulge cells (Jih *et al.*, 1999). The findings that both sporadic TEs and BCCs contain mutations of the *patched* (*ptc*) gene (Johnson *et al.*, 1996) provide compelling evidence that these tumors share a common tumorigenic mechanism and are linked to the hair follicle. The normal expression of *ptc* in the developing hair follicle and the presence of *ptc* mutations in sporadic TEs as well as both hereditary and sporadic BCCs suggest that these tumors arise from a common cell type within the hair follicle. The examination of TEs, BCCs, and other hair follicle tumors with additional markers for hair follicle stem cells should lead to insights into the role stem cells play in the formation of these tumors.

## X. STEM CELLS AND ALOPECIA

Alopecias can be classified into scarring and nonscarring types (Olsen *et al.*, 2003). The localization of hair follicle stem cells to the bulge area may explain why some types of inflammatory alopecias cause permanent follicle loss (such as lichen planopilaris and discoid lupus erythematosus), while others (such as alopecia areata) are reversible (Paus and Cotsarelis, 1999). In cicatricial alopecias, inflammation involves the superficial portion of the follicle, including the bulge area, suggesting that the stem cells necessary for follicle regeneration are damaged. The inflammatory injury of alopecia areata, however, especially in early lesions, involves the bulbar region of the hair follicle, which is composed of bulge cell progeny. Because this area is immediately responsible for hair shaft production, its destruction leads to hair loss. However, the bulge area remains intact, and a new lower anagen follicle and subsequent hair shaft can be produced. Even patients with alopecia areata for many years can regrow their hair either spontaneously or in response to immunomodulation.

The bulge may actually be targeted by inflammation in androgenetic alopecia (common baldness) as well. Jaworsky *et al.* (1992) showed that in patients with early androgenetic alopecia, inflammatory cells localize to the bulge. Over time, this damage could contribute to the irreversible nature of androgenetic alopecia as well. The bulge area appears specifically attacked in early graft-versus-host disease (GVHD), which can cause alopecia (Murphy *et al.*, 1991). These findings are also consistent with the idea that the bulge and lower hair follicle are “immune privileged,” since they express low levels of MHCI.

## XI. BULGE CELLS FOR TISSUE ENGINEERING

An exciting approach for the use of hair follicle stem cells in the treatment of alopecia includes tissue engineering (Stenn and Cotsarelis, 2005). In one scenario, isolated hair follicle stem cells could be used for generating new follicles in bald scalp. For this to occur, isolated bulge cells

must be capable of generating new hair follicles. At least two groups have shown that freshly isolated bulge cells from adult mice, when combined with neonatal dermal cells, formed hair follicles after injection into immunodeficient mice (Blanpain *et al.*, 2004; Morris *et al.*, 2004). These studies provided proof of concept that isolated stem cells could be a part of tissue-engineering approaches for treating alopecia.

A goal for treating alopecia with cell therapy approaches includes increasing the number of follicles, for example, by amplifying the number of stem cells *in vitro* prior to transplantation. Cultured keratinocytes from neonatal epidermis have been used for many years to generate hair follicles in reconstitution assays. Freshly isolated bulge cells from adult mice were shown to form hair follicles in skin-reconstitution assays (Morris *et al.*, 2004). Importantly, cultured, individually cloned bulge cells from adult mice also were shown to form hair follicles in skin-reconstitution assays (Blanpain *et al.*, 2004). However, the ratio of new follicles formed from the number of donor follicles and whether nonbulge keratinocytes also possessed these properties were not analyzed.

The use of hair follicle stem cells for tissue-engineering approaches will depend on the isolation and characterization of human hair follicle stem cells. A major advance in this direction was reported by Ohyama *et al.* (2006). In this work, cell surface markers, including CD200 and FRIZZLED receptor, were identified on human bulge cells by using laser capture microdissection and microarray analysis for gene expression. A cocktail of antibodies against cell surface proteins was devised allowing for isolation of living hair follicle bulge stem cells; thus the stage is set for isolating human hair follicle stem cells to address biological questions relevant to diseases of the follicle and eventually for using these cells for therapeutic purposes.

## XII. MOLECULAR PROFILE — STEM CELL PHENOTYPE

Defining the stem cell phenotype at the molecular level is important for several reasons. Quiescence is a hallmark of these cells. Understanding the genes that distinguish bulge cells from proliferating TA cells as well as the genes that convert resting bulge cells to growing cells bodes well for gaining insights into the uncontrolled proliferation in cancer cells as well as the precisely orchestrated events of hair follicle formation at anagen onset. With the advent of microarrays, large-scale comparisons of gene expression in bulge cells versus nonbulge basal keratinocytes could be performed (Morris *et al.*, 2004; Tumber *et al.*, 2004). These studies, in which bulge cells were isolated by two very different techniques, resulted in reassuringly similar results. At least 60% of the genes reported as differentially expressed by the two groups were the same. Both studies found that genes involved in activation of the WNT pathway were

generally decreased, while inhibitors of this pathway were decreased relative to nonbulge basal keratinocytes. These findings are in line with studies indicating the importance of WNT activation for anagen onset (Van Mater *et al.*, 2003). It is worth noting that large-scale gene-expression studies have been successful in transgenic mice; however, the relevance of the findings to human hair and stem cell biology has only recently been tested (Ohyama *et al.*, 2006). These investigators found many similarities to the mouse studies, thus validating the mouse as a useful model for studying human hair growth. However, very important differences were also described. In particular, CD34, which serves as a mouse bulge cell marker, is not expressed by human hair follicle bulge cells. CD200, a cell surface marker, may be useful for isolating bulge cells. These studies are a major step in our understanding of human hair follicle bulge cells.

Regarding genes that may maintain the stem cell phenotype, functional studies demonstrate that Rac-1 plays an important role in the self-renewal of the epidermis and the hair follicle (Benitah *et al.*, 2005; Dotto and Cotsarelis, 2005). Loss of Rac-1 causes a burst of proliferation in epidermal keratinocytes and then synchronized differentiation and loss of proliferative capability, resulting in thinning of the cutaneous epithelium. Thus, this gene suppresses proliferation and differentiation and seems important for the switch from stem cell to TA cell.

## XIII. THE BULGE AS STEM CELL NICHE

Keratinocytes within the bulge area may depend on their environment or niche for maintaining their stem cell characteristics. The bulge area also houses melanocyte stem cells, which are normally quiescent but proliferate at anagen onset to repopulate the new lower anagen hair follicle with melanocytes that generate melanin, leading to pigmentation of the hair (Nishimura *et al.*, 2002). Intriguingly, there is evidence that the follicle, if not the bulge, serves as a reservoir for immature Langerhans cells as well as other immunocytes (Kumamoto *et al.*, 2003). The role of the bulge environment in maintaining cells of different lineages in a relatively undifferentiated state or instructing (educating?) immune cells needs further study.

## XIV. CONCLUSION

The bulge begins as a prominent structure during human fetal development but then becomes less obvious, thus hindering its study. Markers for bulge cells, such as CD34 expression and K15 promoter activity, allowed for the isolation and characterization of these cells in mouse follicles. Lineage analysis demonstrated that all of the epithelial layers within the adult follicle and hair originate from bulge cells. Bulge cells possess stem cell characteristics, including multipotency, high proliferative potential, and their cardinal feature of quiescence. Although bulge cells only contribute to the epidermis during wound healing, after isolation,

when combined with neonatal dermal cells, they regenerate new hair follicles, epidermis, and sebaceous glands. Propagation of bulge cells *in vitro* maintains their stem cell characteristics, although whether this is an exclusive property of bulge cells remains a question. Under normal homeostatic conditions, epidermal stem cells and hair follicle stem cells

constitute two distinct populations. Understanding the differences between these two types of stem cells as well as for the signals important for directing differentiation of these cells into different lineages will be important for developing treatments based on stem cells as well as for clarifying their role in skin disease.

### I. INTRODUCTION

The skin is the largest organ in the body, and its primary function is to serve as a protective barrier against the environment. Other important functions of the skin include fluid homeostasis, thermoregulation, immune surveillance, sensory detection, and self-healing. Loss of the integrity of large portions of the skin due to injury or illness may result in significant disability or even death. It is estimated that in 1992, there were 35.2 million cases of significant skin loss (Wound Care, 1993) that required major therapeutic intervention. Of these, approximately 7 million wounds become chronic.

The most common single cause of significant skin loss is thermal injury, which accounts for an estimated 1 million emergency room visits per year (American Burn Association, 2005). Other causes of skin loss include trauma (35 million wounds/yr in the United States require therapeutic intervention) and chronic ulcerations secondary to diabetes mellitus, pressure, and venous stasis. Every year in the United States there are approximately 2 million cases of chronic diabetic ulcers, many of which eventually necessitate amputation. Pressure ulcers and leg ulcers, including venous ulcers, affect another 2 million people in the United States, with treatment costs as high as \$8 billion annually (Supp and Boyce, 2005). Of these approximately 600,000 patients suffer from venous ulcers, at an average cost of \$9685 per patient (Olin *et al.*, 1999). In 2003, a survey estimated the U.S. market for advanced wound care products,

including biological and synthetic dressings, to be greater than \$1.7 billion, which is expected to increase significantly as the population ages, becoming more susceptible to underlying causes of chronic wounds. The quality-of-life tolls of chronic wounds are extremely high.

Over the past two decades, extraordinary advances in cellular and molecular biology have greatly expanded our comprehension of the basic biological processes involved in acute-wound healing and the pathobiology of chronic wounds (Singer and Clark, 1999; Mustoe, 2004). These strides in basic knowledge have led to advancements in wound care resulting in more rapid closure of ulcers and normal wounds. Furthermore, since tumor microenvironments have many similarities to wound healing (Dvorak, 1986), increased knowledge in wound healing (Ashcroft *et al.*, 2003) has led to advances in tumor therapy (Basu *et al.*, 2006). For wound therapy, one recombinant growth factor, platelet-derived growth factor-BB (rPDGF-BB) (Regranex, Ortho-McNeil), and several skin substitutes (Dermagraft and TransCyte, Advance Tissue Sciences; Apligraf, Organogenesis; Integra Matrix Wound Dressings, Integra LifeSciences Holding; OrCel, Ortec International; AlloDerm, LifeCell) have reached the marketplace for second-line therapy of recalcitrant ulcers (Singer and Clark, 1999; Balasubramani *et al.*, 2001). These therapeutic interventions can successfully improve the rate of wound closure. Unfortunately, rPDGF-BB must be applied daily, forcing patients to change their bandages daily, and two companies

producing skin substitutes have undergone bankruptcy and reorganization. Regardless of the advanced wound care product, the ideal goal would be to regenerate tissues where both the structural and functional properties of the wounded tissue are restored to their levels prior to injury.

In contrast to adult wounds, embryonic wounds undergo complete regeneration, terminating in a scarless repair (Martin and Parkhurst, 2004; Redd *et al.*, 2004). Morphogenetic cues from this embryonic phenotype should be utilized to develop engineered constructs capable of tissue regeneration. Furthermore, the cellular response to biological stimuli depends on the mechanical strength of the extracellular matrix (ECM) (Grinnell, 2003; Vogel and Sheetz, 2006). Therefore, the therapeutic successes of tissue-engineered constructs will depend not only on their bioactivity but also on their optimal mechanical properties.

This chapter begins with an overview of the basic biology of wound repair, followed by a discussion of established practices and novel approaches to engineering tissue constructs for effective wound repair.

## II. BASIC BIOLOGY OF WOUND REPAIR

Wound repair is not a simple linear process in which growth factors released by phylogistic events activate parenchymal cell proliferation and migration; rather, it is an integration of dynamic interactive processes involving soluble mediators, formed blood elements, extracellular matrix, and parenchymal cells. Unencumbered, these wound repair processes follow a specific time sequence and can be temporally categorized into three major groups: inflammation, tissue formation, and tissue remodeling. The three phases of wound repair, however, are not mutually exclusive but, rather, overlap in time.

### Inflammation

Severe tissue injury causes blood vessel disruption, with concomitant extravasation of blood constituents. Blood coagulation and platelet aggregation generate a fibrin-rich clot that plugs severed vessels and fills any discontinuity in the wounded tissue. While the blood clot within vessel lumen reestablishes homeostasis, the clot within wound space acts as a growth factor reservoir and provides a provisional matrix for cell migration.

The primary cell types involved in the overall process of inflammation are platelets, neutrophils, and monocytes. Upon injury, successful reestablishment of homeostasis depends on platelet adhesion to interstitial connective tissue, which leads to their aggregation, coagulation, and activation. Activated platelets release several adhesive proteins to facilitate their aggregation, chemotactic factors for blood leukocytes, and multiple growth factors to promote new-tissue formation.

Of the two primary phagocytotic leukocytes (neutrophils and monocytes), neutrophils arrive first in large numbers due to their abundance in circulation. Infiltrating neutrophils cleanse the wounded area of foreign particles, including bacteria. If excessive microorganisms or indigestible particles have lodged in the wound site, neutrophils will probably cause further tissue damage as they attempt to clear these contaminants through the release of enzymes and toxic oxygen products. When particle clearance has been completed, generation of granulocyte chemoattractants ceases and the remaining neutrophils become effete.

### Transition Between Inflammation and Repair

Whether neutrophil infiltrates resolve or persist, monocyte accumulation continues, stimulated by selective monocyte chemoattractants (Clark, 1996). Besides promoting phagocytosis and debridement, adherence to extracellular matrix stimulates monocytes to undergo metamorphosis into inflammatory or reparative macrophages. Since cultured macrophages produce and secrete the peptide growth factors interleukin-1 (IL-1), platelet-derived growth factor-BB (PDGF-BB), transforming growth factor alpha (TGF- $\alpha$ ), transforming growth factor beta (TGF- $\beta$ ), and fibroblast growth factor (FGF), presumably wound macrophages also synthesize these protein products (Clark, 1996). Although neutrophils and macrophages have a critical role in fighting infection and macrophages can contribute growth factors to the wound, it has become increasingly clear that too much of a good thing can be bad (Martin and Leibovich, 2005). In fact, from knockout and knockdown experiments, it is evident that wounds in some situations heal faster with fewer inflammatory cells, especially if microorganism invasion is avoided by some other means (Ashcroft *et al.*, 1999).

### Re-epithelialization

Re-epithelialization of a wound begins within hours after injury by the movement of epithelial cells from the surrounding epidermis over the denuded surface. Rapid reestablishment of the epidermal surface and its permeability barrier prevents excessive water loss and time of exposure to bacterial infections, which decreases the morbidity and mortality of patients who have lost a substantial amount of skin surface. If a wide expanse of the epidermis is lost, epidermal cells regenerate from stem cells in pilosebaceous follicles (Cotsarelis, 2006). Migrating epithelial cells markedly alter their phenotype by retracting their intracellular filaments, dissolving most of their desmosomes, and forming peripheral actin filaments (which facilitate cell movement) (Clark, 1996). These migrating cells also undergo dissolution of their hemidesmosomal links between the epidermis and the dermis. All these phenotypic alterations provide epithelial cells with the needed lateral mobility for migration over the wound site. Migrating epidermal cells possess a unique phenotype that is distinct from both the terminally differ-

**Table 76.1.** Integrin superfamily

<i>Integrins</i>	<i>Ligand</i>	<i>Integrins</i>	<i>Ligand</i>
<b><math>\beta 1</math> Integrins</b>		<b><math>\alpha v</math> Integrins</b>

<b>Other ECM integrins</b>			
$\alpha IIb\beta 3$	Same as $\alpha v\beta 3$		
$\alpha 6\beta 4$	Laminin		

entiated keratinocytes of normal (stratified) epidermis and the basal cells of stratified epidermis. It is now appreciated that the signals that control wound healing in the adult animal are similar to those that control epithelial fusion during embryogenesis (Jacinto *et al.*, 2001).

If the basement membrane is destroyed by injury, epidermal cells migrate over a provisional matrix of fibrin(ogen), fibronectin, tenascin, and vitronectin as well as stromal type I collagen (Clark, 1996). Wound keratinocytes express cell surface receptors for fibronectin, tenascin, and vitronectin, which belong to the integrin superfamily (Table 76.1) (Yamada *et al.*, 1996). In addition,  $\alpha 2\beta 1$  collagen receptors, which are normally disposed along the lateral sides of basal keratinocytes, redistribute to the basal membrane of wound keratinocytes as they come in contact with type I collagen fibers of the dermis. Whereas  $\beta 1$  integrins are clearly essential for normal re-epithelialization (Grose *et al.*, 2002), it is not clear which subtype is essential. It is most likely that there is a redundancy in the requirement for  $\alpha 5\beta 1$  and  $\alpha 2\beta 1$  in re-epithelialization.

The migrating wound epidermis does not simply transit over a wound coated with a fibrin/fibronectin provisional matrix but, rather, dissects through the wound, separating the clot and desiccated or otherwise nonviable tissue from underlying viable tissue (Kubo *et al.*, 2001). The path of dissection appears to be determined by the array of integrins that the migrating epidermal cells express on their cell membranes, as described previously. In addition, the  $\alpha v\beta 3$  receptor for fibrinogen/fibrin and denatured collagen are not expressed on keratinocytes *in vitro* or *in vivo*. Therefore, keratinocytes do not have the capacity to interact with these matrix proteins. Furthermore, in the presence of fibrinogen or fibrin, epidermal cells fail to bind fibronectin yet can bind

**FIG. 76.1.** Integrins in early (three-dimensional) reepithelialization. The migrating epidermis in contact with type I dermal collagen expresses a gene set including the collagen receptor  $\alpha 2\beta 1$ , urokinase plasminogen activator (uPA), and interstitial collagenase (MMP-1). With this armamentarium, the epidermis can dissect a path between viable dermis and nonviable clot and denature stroma, ultimately leading to slough of the eschar.

type I collagen. Hence, migrating wound epidermis avoids the fibrin-rich, fibronectin-rich clot while migrating over a bed of fibronectin (via the  $\alpha 5\beta 1$  receptor) and type I collagen (via the  $\alpha 2\beta 1$  receptor) (Fig. 76.1).

Extracellular matrix degradation is clearly required for the dissection of migrating wound epidermis between the collagenous dermis and the fibrin eschar (Bugge *et al.*, 1996) and probably depends on epidermal cell production of collagenase, plasminogen activator, and stromelysin. Plasminogen activator activates collagenase (MMP-1) as well as plasminogen (Mignatti *et al.*, 1996) and therefore facilitates the degradation of interstitial collagen as well as provisional matrix proteins. Interestingly, keratinocytes in direct contact with collagen greatly increase the amount of MMP-1 they produce as compared to that produced when they reside on laminin-rich basement membrane or purified laminin

(Petersen *et al.*, 1990). The migrating epidermis of superficial skin ulcers and burn wounds, in fact, express high levels of MMP-1 mRNA in areas where it presumably comes in direct contact with dermal collagen (Saarialho-Kere *et al.*, 1992; Stricklin and Nanney, 1994).

One to two days after injury, epithelial cells at the wound margin begin to proliferate. Although the exact mechanism is still not clear, both proliferation and migration of epithelial cells may be triggered by the absence of neighboring cells at the wound margin (or the “free-edge effect”). The free edge effect in the wound epidermis may be secondary to modulation of cadherin junctions, as described for V-cadherins during angiogenesis (Dejana, 1996). In fact, recent studies indicate that epidermal desmosomes lose their hyperadhesiveness and cadherins switch from E-cadherins to P-cadherins at the wound edge (Garrod *et al.*, 2005; Koizumi *et al.*, 2005). Other possibilities, not exclusive of the former, are release of autocrine or paracrine growth factors that induce epidermal migration and proliferation and/or increased expression of growth factor receptors. Although some growth factors, such as insulin-like growth factor (IGF), may derive from the circulation and thereby act as a hormone, other growth factors, such as heparin-binding epidermal growth factor (HB-EGF) and keratinocyte growth factor (KGF), derive from macrophages and dermal parenchymal cells, respectively, and act on epidermal cells through a paracrine pathway (Werner, 1998). In contrast, transforming growth factor (TGF)- $\alpha$  and - $\beta$  originate from keratinocytes themselves and act directly on the producer cell or adjacent epidermal cells in an autocrine or juxtacrine fashion. Many of these growth factors have been shown to stimulate re-epithelialization in animal models (Brown *et al.*, 1989; Lynch *et al.*, 1989; Staiano-Coico *et al.*, 1993). Furthermore, lack of growth factors or their receptors in knockout mice support the hypothesis that growth factor activation of keratinocytes is required for optimal epidermal migration and/or proliferation during normal wound healing (Grose and Werner, 2004). Recently it has been demonstrated that JNK is a key signal transduction factor responsible for “re-setting” the epidermal program from differentiation to proliferation and possibly migration (Gazel *et al.*, 2006).

As re-epithelialization progresses, basement membrane proteins reappear in a very ordered sequence from the margin of the wound inward, in a zipperlike fashion (Clark, 1996). Epidermal cells revert to their normal phenotype, once again firmly attaching to re-established basement membrane through hemidesmosomal proteins  $\alpha 6 \beta 4$  integrin and 180-kDa bullous pemphigoid antigen (Litjens *et al.*, 2006), and to the underlying neodermis through type VII collagen fibrils (El Ghalbzouri *et al.*, 2004).

## Granulation Tissue

New stroma, often called *granulation tissue*, begins to form approximately four days after injury. The name derives from the granular appearance of newly forming tissue when it is incised and visually examined. Numerous new capillar-

ies endow the neostroma with its granular appearance. Macrophages, fibroblasts, and blood vessels move into the wound space as a unit (Hunt, 1980), which correlates well with the proposed biologic interdependence of these cells during tissue repair. Macrophages and ingrowing parenchymal cells provide a continuing source of cytokines necessary to stimulate fibroplasia and angiogenesis, fibroblasts construct new extracellular matrix necessary to support cell ingrowth, and blood vessels carry oxygen and nutrients necessary to sustain cell metabolism. Recently the importance of oxygenation has been re-emphasized (Hopf *et al.*, 2005; Ueno *et al.*, 2006). The quantity and quality of granulation tissue depends on the biologic modifiers present, the activity level of target cells, and the extracellular matrix environment (Juliano and Haskill, 1993). As mentioned in the section on inflammation, the arrival of peripheral blood monocytes and their activation to macrophages establish conditions for continual synthesis and release of growth factors. In addition, and perhaps more importantly, injured and activated parenchymal cells can synthesize and secrete growth factors. For example, migrating wound epidermal cells produce vascular endothelial cell growth factor (VEGF) (Kishimoto *et al.*, 2000), TGF- $\beta$  (Frank *et al.*, 1996), and PDGF-BB (Ansel *et al.*, 1993), to which endothelial cells and fibroblasts respond, respectively. The provisional ECM also promotes granulation-tissue formation by positive feedback regulation of integrin ECM receptor expression (Xu and Clark, 1996). Once fibroblasts and endothelial cells express the appropriate integrin receptors, they invade the fibrin-rich/fibronectin-rich wound space (Fig. 76.2). Although it has been recognized for many years that ECM modulates cell differentiation via signal transduction from ligation of ECM receptors (Lin and Bissell, 1993; Nelson and Bissell, 2005), more recently it has become evident that the force and geometry of the ECM influence cell behavior and differentiation (Ingber, 2003; Discher *et al.*, 2005; Vogel and Sheetz, 2006).

## Fibroplasia

Components of granulation tissue derived from fibroblasts, including the cells themselves and the extracellular matrix, are collectively known as *fibroplasia*. Growth factors, especially PDGF and TGF- $\beta$  (Heldin, 1996; Roberts and Sporn, 1996), in concert with the provisional matrix molecules (Xu and Clark, 1996), presumably stimulate fibroblasts of the periwound tissue to proliferate, express appropriate integrin receptors, and migrate into the wound space. Many of these growth factors are released from macrophages (Clark, 1996) or other tissue cells (Ansel *et al.*, 1993; Frank *et al.*, 1996); however, fibroblasts themselves can produce growth factors to which they respond in an autocrine fashion (Pardoux and Derynck, 2004). Multiple complex interactive biologic phenomena occur within fibroblasts as they respond to wound cytokines, including the induction of additional cytokines and modulation of cytokine receptor number or affinity. *In vivo* studies support the hypothesis

**FIG. 76.2.** After injury, platelets, inflammatory cells, and tissue cells (i.e., fibroblasts and endothelial and epidermal cells) secrete abundant quantities of multiple growth factors thought to be necessary for cell movement into the wound. However, it is the provisional matrix and integrin expression that acts as the rate-limiting step in granulation-tissue induction. Once the appropriate integrins are expressed on periwound endothelial cells and fibroblasts on day 3, the cells invade the wound space shortly thereafter (days 4 and 5). Fibroblasts and endothelial cells express the fibrinogen/fibrin receptor  $\alpha V\beta 3$  and therefore are able to invade the fibrin clot; the epidermis, however, does not express  $\alpha V\beta 3$  and therefore dissects under the clot. Proteinases play an important role during granulation-tissue formation by clearing the path for migrating tissue cells. Ultimately, the clot that has not been transformed into granulation tissue by invading fibroblasts and endothelial cells is dissected free of the wound by the migrating epidermis and sloughed as eschar. Modified from Singer, A. J., and Clark, R. A. F. (1999). Mechanisms of disease: cutaneous wound healing. *New Eng. J. Med.* **341**, 738–746, with permission.

that growth factors are active in wound repair fibroplasia. Several studies have demonstrated that PDGF, connective tissue factor (CTGF), TGF- $\alpha$ , TGF- $\beta$ , HB-EGF, and FGF family members are present at sites of tissue repair (Pierce *et al.*, 1992; Werner *et al.*, 1992; Ansel *et al.*, 1993; Levine *et al.*, 1993; Marikovsky *et al.*, 1993; Frank *et al.*, 1996; Grotendorst and Duncan, 2005). Furthermore, purified and recombinant-derived growth factors have been shown to stimulate wound granulation tissue in normal and compromised animals (Greenhalgh *et al.*, 1990; Mustoe *et al.*, 1991; Steed *et al.*, 1992; Shah *et al.*, 1995), and a single growth factor may work both directly and indirectly by inducing the production of other growth factors *in situ* (Mustoe *et al.*, 1991).

Structural molecules of the early ECM, coined *provisional matrix* (Clark *et al.*, 1982), contribute to tissue formation by providing a scaffold or conduit for cell migration (fibronectin) (Greiling and Clark, 1997), low impedance for cell mobility (hyaluronic acid) (Toole, 1991), a reservoir for cytokines (Wijelath *et al.*, 2002; Sahni *et al.*, 2006), and direct signals to the cells through integrin receptors (Juliano *et al.*, 2004; Ginsberg *et al.*, 2005; Walker and Assoian, 2005). Fibronectin appearance in the periwound environment as well as the expression of fibronectin receptors appear to be critical rate-limiting steps in granulation-tissue formation (Clark *et al.*, 1996; McClain *et al.*, 1996; Xu and Clark, 1996; Greiling and Clark, 1997). In addition, a dynamic reciprocity between fibroblasts and their surrounding ECM creates further com-

plexity. That is, fibroblasts affect the ECM through new synthesis, deposition, and remodeling of the ECM, while the ECM affects fibroblasts by regulating their function, including their ability to synthesize, deposit, remodel, and generally interact with the ECM (Clark *et al.*, 1995; Xu and Clark, 1996; Grinnell, 2003; Even-Ram and Yamada, 2005). Thus, the reciprocal interactions between ECM and fibroblasts evolve dynamically during granulation-tissue development.

As fibroblasts migrate into the wound space, they initially penetrate the blood clot, composed of fibrin and lesser amounts of fibronectin and vitronectin. Fibroblasts presumably require fibronectin *in vivo* for movement from the periwound collagenous matrix into the fibrin/fibronectin-laden wound space, as they do *in vitro* for migration from a three-dimensional collagen gel into a fibrin gel (Greiling and Clark, 1997). Fibroblasts bind to fibronectin through receptors of the integrin superfamily (Table 76.1) (Yamada *et al.*, 1996). The Arg-Gly-Asp-Ser (RGDS) tetrapeptide within the cell-binding domain of these proteins is critical for binding to the integrin receptors  $\alpha 3\beta 1$ ,  $\alpha 5\beta 1$ ,  $\alpha v\beta 1$ ,  $\alpha v\beta 3$ , and  $\alpha v\beta 5$ . In addition, the CSIII domain of fibronectin provides a second binding site for human dermal fibroblasts via the  $\alpha 4\beta 1$  integrin receptor (Gailit *et al.*, 1993). *In vivo* studies have shown that the RGD-dependent fibronectin receptors  $\alpha 5\beta 1$  and  $\alpha v\beta 3$  are up-regulated on periwound fibroblasts the day prior to granulation tissue formation and on early granulation-tissue fibroblasts as they infiltrate the provisional matrix-laden wound (Xu and Clark, 1996). In contrast, the non-RGD-binding  $\alpha 1\beta 1$  and  $\alpha 2\beta 1$  collagen receptors on these fibroblasts either were suppressed or did not appear to change appreciably (Gailit *et al.*, 1996; Xu and Clark, 1996).

Both PDGF and TGF- $\beta$  can stimulate fibroblasts to migrate (Postlethwaite *et al.*, 1987) and can up-regulate integrin receptors (Heino *et al.*, 1989; Gailit *et al.*, 1996). Therefore, these growth factors appear to be responsible for inducing a migrating fibroblast phenotype. However, PDGF increases  $\alpha 5\beta 1$  and  $\alpha 3\beta 1$  while decreasing  $\alpha 1\beta 1$  in cultured human dermal fibroblasts surrounded by fibronectin (Gailit *et al.*, 1996). Furthermore, fibronectin- or fibrin-rich environments promote the ability of PDGF to increase  $\alpha 5\beta 1$  and  $\alpha 3\beta 1$ , but not  $\alpha 2\beta 1$ , mRNA steady-state levels by increasing the stability of these mRNA moieties (Xu and Clark, 1996). These data strongly suggest that the type of integrin increased by PDGF stimulation appears to depend on the ECM context and suggests a positive feedback between ECM and ECM receptors.

Movement into a cross-linked fibrin blood clot or any tightly woven extracellular matrix may also necessitate active proteolysis to cleave a path for migration. A variety of fibroblast-derived enzymes in conjunction with serum-derived plasmin are potential candidates for this task, including plasminogen activator, interstitial collagenase-1 and -3 (MMP-1 and MMP-13, respectively), the 72-kDa gela-

tinase A (MMP-2), and stromelysin (MMP-3) (Mignatti *et al.*, 1996; Vaalamo *et al.*, 1997). In fact, high levels of immunoreactive MMP-1 have been localized to fibroblasts at the interface of granulation tissue with eschar in burn wounds (Stricklin and Nanney, 1994), and many stromal cells stain for MMP-1 and MMP-13 in chronic ulcers (Vaalamo *et al.*, 1997). While TGF- $\beta$  down-regulates proteinase activity (Overall *et al.*, 1989), PDGF stimulates the production and secretion of these proteinases (Circolo *et al.*, 1991).

From elegant knockout mice studies it is clear that the plasminogen activator-plasminogen system is critical for clearing the wound clot (Bugge *et al.*, 1996). Whereas MMP-9-deficient mice demonstrate altered fracture repair (Colnot *et al.*, 2003), results of MMP deficiency in genetically manipulated mice has not been so clear for soft-tissue healing. Neither deficiency of membrane-type-1 MMP, an activator of MMP-1, -3, -2, -9, and -13, nor deficiency of MMP-13 itself led to abnormal cutaneous wound healing (Mirastschijski *et al.*, 2004; Hartenstein *et al.*, 2006).

Once the fibroblasts have migrated into the wound, they gradually switch their major function to protein synthesis (Welch *et al.*, 1990). Ultimately the migratory phenotype is completely supplanted by a profibrotic phenotype characterized by decreased  $\alpha 3\beta 1$  and  $\alpha 5\beta 1$  provisional matrix receptor expression, increased  $\alpha 2\beta 1$  collagen receptor expression, abundant rough endoplasmic reticulum, and Golgi apparatus filled with new collagen protein (Welch *et al.*, 1990; Xu and Clark, 1996). The fibronectin-rich provisional matrix is gradually supplanted with a collagenous matrix (Welch *et al.*, 1990; Clark *et al.*, 1995). Under these conditions, PDGF, which is still abundant in these wounds (Pierce *et al.*, 1995), stimulates extremely high levels of  $\alpha 2\beta 1$  collagen receptor, but not  $\alpha 3\beta 1$  or  $\alpha 5\beta 1$  provisional matrix receptors, supporting the contention that the extracellular matrix provides a positive feedback for integrin expression (Xu and Clark, 1996). TGF- $\beta$ , which is observed in wound fibroblasts at this time (Clark *et al.*, 1995), can induce fibroblasts to produce great quantities of collagen (Ignatz and Massague, 1986; Roberts *et al.*, 1986). IL-4 also can induce a modest increase in types I and III collagen production (Postlethwaite *et al.*, 1992). Since IL-4-producing mast cells are present in healing wounds as well as in fibrotic tissue, they may contribute to collagenous matrix accumulation in these sites.

Once an abundant collagen matrix is deposited in the wound, fibroblasts cease collagen production, despite the continuing presence of TGF- $\beta$  (Clark *et al.*, 1995). The stimuli responsible for fibroblast proliferation and matrix synthesis during wound repair were originally extrapolated from many *in vitro* investigations over the past quarter-century and then confirmed by *in vivo* manipulation of wounds within the last 15 years. Less attention had been directed toward elucidating the signals responsible for down-regulating fibroblast proliferation and matrix synthesis until more recently. Both *in vitro* and *in vivo* studies suggest

that gamma-interferon may be one such factor (Duncan and Berman, 1985; Granstein *et al.*, 1987). In addition, collagen matrix can suppress both fibroblast proliferation and fibroblast collagen synthesis (Grinnell, 1994; Clark *et al.*, 1995). In contrast, a fibrin or fibronectin matrix has little or no suppressive effect on the mitogenic or synthetic potential of fibroblasts (Clark *et al.*, 1995; Tuan *et al.*, 1996).

Although the attenuated fibroblast activity in collagen gels is not associated with cell death, many fibroblasts in day-10 healing wounds develop pyknotic nuclei (Desmouliere *et al.*, 1995), a cytological marker for apoptosis, or programmed cell death, as well as other signs of apoptosis. These results in cutaneous wounds and other results in lungs and kidney suggest that apoptosis is the mechanism responsible for the transition from a fibroblast-rich granulation tissue to a relatively acellular scar (Desmouliere *et al.*, 1997). The signal(s) for wound fibroblast apoptosis have not been elucidated. Thus fibroplasia in wound repair is tightly regulated, whereas in fibrotic diseases such as keloid formation, morphea, and scleroderma these processes become dysregulated. Recent evidence suggests that the fibroblast apoptotic signals in keloids are disrupted either directly or indirectly (Moulin *et al.*, 2004; Linge *et al.*, 2005).

### Neovascularization

Fibroplasia would halt if neovascularization failed to accompany the newly forming complex of fibroblasts and extracellular matrix. The process of new blood vessel formation is called *angiogenesis*. The soluble factors that can stimulate angiogenesis in wound repair are gradually being elucidated. Angiogenic activity can be recovered from activated macrophages as well as various tissues, including the epidermis, soft-tissue wounds, and solid tumors. Molecules that appear to have angiogenic activity include vascular endothelial growth factor (VEGF), TGF- $\beta$ , TGF- $\alpha$ , TNF- $\alpha$ , platelet factor-4 (PF-4), angiogenin, angiotropin, angiopoietin, interleukin-8 (IL-8), PDGF, thrombospondin, low-molecular-weight substances, including the peptide KGHK, low oxygen tension, biogenic amines, and lactic acid and nitric oxide (NO). Some of these factors, however, are intermediaries in a single angiogenesis pathway; for example, TNF- $\alpha$  induces PF-4, which stimulates angiogenesis through NO (Montrucchio *et al.*, 1997). To complicate matters further, not all growth factors within a family stimulate angiogenesis equally. For example, there are four isoforms of VEGF (VEGF-A, -B, -C, and -D) and three receptors (VEGFR1/Flt-1, VEGFR2/KDR/Flk-1, and VEGFR3) (Olsson *et al.*, 2006). VEGF-A does not interact with VEGFR1 and VEGFR2 equally, and the signal transduction stimulated is not the same. Furthermore, VEGF-C and -D stimulate lymphangiogenesis through VEGFR3 during development and solid tumor formation. Another complexity is that different growth factors affect blood vessel development at different stages. For example, VEGF-A

stimulates nascent sprout angiogenesis, while angiopoietin induces blood vessel maturation (Eklund and Olsen, 2006) and protects mature blood vessels (Brindle *et al.*, 2006).

Angiogenesis cannot be related directly to proliferation of cultured endothelial cells. In fact, Folkman (Folkman and Shing, 1992) has postulated that endothelial cell migration can induce proliferation. If this is true, endothelial cell chemotactic factors may be critical for angiogenesis. Some factors, of course, may have both mitogenic and chemotactic activities. For example, PDGF and EGF can be both chemotactic and mitogenic for dermal fibroblasts, while VEGF can be both mitogenic and chemotactic for endothelial cells (Nissen *et al.*, 1998; Zachary, 2003; Gallicchio *et al.*, 2005).

Besides growth factors and chemotactic factors, an appropriate extracellular matrix is necessary for angiogenesis. Three-dimensional gels of extracellular matrix proteins have more pronounced effects on cultured endothelial cells than do monolayer protein coats (Tonnesen *et al.*, 2000), as has been observed with smooth muscle cells (Koyama *et al.*, 1996). Rat epididymal microvascular cells cultured in type I collagen gels with TGF- $\beta$  produce capillary-like structures within one week (Madri *et al.*, 1996). Omission of TGF- $\beta$  markedly reduces the effect. In contrast, laminin-containing gels in the absence of growth factors induce human umbilical vein and dermal microvascular cells to produce capillary-like structures within 24 hours of plating (Kubota *et al.*, 1988). Matrix-bound thrombospondin also promotes angiogenesis (Nicosia and Tuszynski, 1994), possibly through its ability to activate TGF- $\beta$ . Recently it has been observed that type I collagen can protect newly formed blood vessels from apoptotic effects of angiostatic agents (Addison *et al.*, 2005). Together, these studies support the hypothesis that the extracellular matrix plays an important role in angiogenesis. Consonant with this hypothesis, angiogenesis in the chick chorioallantoic membrane is dependent on the expression of  $\alpha v \beta 3$ , an integrin that recognizes fibrin and fibronectin as well as vitronectin (Brooks, Clark *et al.*, 1994). Furthermore, in porcine cutaneous wounds,  $\alpha v \beta 3$  is expressed only on capillary sprouts as they invade the fibrin clot (Clark *et al.*, 1996). *In vitro* studies in fact demonstrate that  $\alpha v \beta 3$  can promote endothelial cell migration on provisional matrix proteins (Leavesley *et al.*, 1993).

Given the information just outlined, a series of events leading to angiogenesis can be hypothesized. Substantial injury causes tissue-cell destruction and hypoxia. Potent angiogenesis factors such as FGF-1 and FGF-2 are released secondary to cell disruption, while VEGF is induced by hypoxia. Proteolytic enzymes released into the connective tissue degrade extracellular matrix proteins. Specific fragments from collagen, fibronectin, and elastin as well as many phylogenic agents recruit peripheral blood monocytes to the injured site, where these cells become activated macrophages that release more angiogenesis factors. Certain

angiogenic factors, such as FGF-2, stimulate endothelial cells to release plasminogen activator and procollagenase. Plasminogen activator converts plasminogen to plasmin and procollagenase to active collagenase, and in concert these two proteases digest basement membrane constituents.

The fragmentation of the basement membrane allows endothelial cells to migrate into the injured site in response to FGF, fibronectin fragments, heparin released from disrupted mast cells, and other endothelial cell chemoattractants. To migrate into the fibrin/fibronectin-rich wound, endothelial cells express  $\alpha v \beta 3$  integrin. The newly forming blood vessels first deposit a provisional matrix containing fibronectin and proteoglycans but ultimately form basement membrane. TGF- $\beta$  may induce endothelial cells to produce the fibronectin and proteoglycan provisional matrix as well as to assume the correct phenotype for capillary-tube formation. FGF and other mitogens, such as VEGF, stimulate endothelial cell proliferation, resulting in a continual supply of endothelial cells for capillary extension. Capillary sprouts eventually branch at their tips and join to form capillary loops through which blood flow begins. New sprouts then extend from these loops to form a capillary plexus.

Within a day or two after removal of angiogenic stimuli, capillaries undergo regression, as characterized by mitochondrial swelling in the endothelial cells at the distal tips of the capillaries, platelet adherence to degenerating endothelial cells, vascular stasis, endothelial cell necrosis, and ingestion of the effete capillaries by macrophages. Although  $\alpha v \beta 3$  has been shown to regulate apoptosis of endothelial cells in culture and in tumors (Brooks *et al.*, 1994),  $\alpha v \beta 3$  is not present on wound endothelial cells as they undergo programmed cell death, indicating another pathway of apoptosis in healing-wound blood vessels (X. Feng, R. A. F. Clark, and M. G. Tonnesen, unpublished observations). Thrombospondin appears to be a good candidate for this phenomenon (Koch *et al.*, 1992).

### Wound Contraction and Extracellular Matrix Organization

During the second and third weeks of healing, fibroblasts begin to assume a myofibroblast phenotype characterized by large bundles of actin-containing microfilaments disposed along the cytoplasmic face of the plasma membrane and the establishment of cell-cell and cell-matrix linkages (Welch *et al.*, 1990; Hinz *et al.*, 2004). In some (Desmouliere *et al.*, 1995) but not all (Welch *et al.*, 1990) wound situations, myofibroblasts express smooth muscle actin. Importantly, TGF- $\beta$  can induce cultured human fibroblasts to express smooth muscle actin (Desmouliere *et al.*, 1993) and may also be responsible for its expression *in vivo* (Gabbiani, 2003).

The appearance of the myofibroblasts corresponds to the commencement of connective tissue compaction and

the contraction of the wound. Fibroblasts link to the extracellular fibronectin matrix through  $\alpha 5 \beta 1$  (Welch *et al.*, 1990); to collagen matrix through  $\alpha 1 \beta 1$  and  $\alpha 2 \beta 1$  collagen receptors (Ignatius *et al.*, 1990); and to each other through direct adherens junctions (Welch *et al.*, 1990). Fibroblast  $\alpha 2 \beta 1$  receptors are markedly up-regulated in seven-day wounds (Xu and Clark, 1996), a time when new collagenous matrix is accumulating and fibroblasts are beginning to align with collagenous fibrils through cell-matrix connections (Welch *et al.*, 1990). New collagen bundles in turn have the capacity to join end-to-end with collagen bundles at the wound edge and ultimately to form covalent cross-links among themselves and with the collagen bundles of the adjacent dermis (Yamauchi *et al.*, 1987; Birk *et al.*, 1989). These cell-cell, cell-matrix, and matrix-matrix links provide a network across the wound whereby the traction of myofibroblasts on their pericellular matrix can be transmitted across the wound (Hinz, 2006).

Cultured fibroblasts dispersed within a hydrated collagen gel provide a functional *in vitro* model of tissue contraction (Bell *et al.*, 1979; Carlson and Longaker, 2004). When serum is added to the admixture, contraction of the collagen matrix occurs over the course of a few days. When observed with time-lapse microphotography, collagen condensation appears to result from a "collection of collagen bundles" executed by fibroblasts as they extend and retract pseudopodia attached to collagen fibers (Bell *et al.*, 1979). More recent elegant studies have further defined fibroblast-collagen interactions (Grinnell *et al.*, 2006). The transmission of these traction forces across the *in vitro* collagen matrix depends on two linkage events: fibroblast attachment to the collagen matrix through the  $\alpha 2 \beta 1$  integrin receptors (Schirotto *et al.*, 1991) and cross-links between the individual collagen bundles (Woodley *et al.*, 1991). This linkage system probably plays a significant role in the *in vivo* situation of wound contraction as well. In addition, cell-cell adhesions appear to provide an additional means by which the traction forces of the myofibroblast may be transmitted across the wound matrix (Hinz *et al.*, 2004).

F-actin bundle arrays, cell-cell and cell-matrix linkages, and collagen cross-links are all facets of the biomechanics of extracellular matrix contraction. The contraction process, however, needs a cytokine signal. For example, cultured fibroblasts mixed in a collagen gel contract the collagen matrix in the presence of serum (Bell *et al.*, 1979), PDGF (Clark *et al.*, 1989), or TGF- $\beta$  (Werner *et al.*, 1994). Since TGF- $\beta$  (Clark *et al.*, 1995), but not PDGF (Marikovsky *et al.*, 1993), persists in dermal wounds during the time of tissue contraction, it is the most likely candidate for the stimulus of contraction. Nevertheless, it is possible that both PDGF and TGF- $\beta$  signal wound contraction, one more example of the many redundancies observed in the critical processes of wound healing. In summary, wound contraction represents a complex and masterfully orchestrated interaction of cells, extracellular matrix, and cytokines.

Collagen remodeling during the transition from granulation tissue to scar is dependent on continued collagen synthesis and collagen catabolism. The degradation of wound collagen is controlled by a variety of collagenase enzymes from macrophages, epidermal cells, and fibroblasts. These collagenases are specific for particular types of collagens, but most cells probably contain two or more different types of these enzymes (Mott and Werb, 2004). Three metalloproteinases (MMPs) have been described that have the ability to cleave native collagen: MMP-1, or classic interstitial collagenase, which cleaves types I, II, III, XIII, and X collagens; neutrophil collagenase (MMP-8); and a novel collagenase produced by breast carcinomas that is prominent in chronic wounds (MMP-13) (Vaalamo *et al.*, 1997). Currently it is not known which *interstitial* collagenases are critical in the remodeling stage of human wound repair. For example, no wound-healing defect was observed in mice deficient for MMP-13 (Hartenstein *et al.*, 2006). However, this fact may be attributable to the redundancy of nature.

Other MMPs potentially important in wound repair include two gelatinases, 72-kDa gelatinase A (MMP-2) and 92-kDa gelatinase B (MMP-9), with identical substrate specificity to degrade denatured collagens of all types as well as native types V and XI collagens; and stromelysin-1, -2, and -3, which degrade a wide variety of substrates, including types III, IV, V, VII, and IX collagens as well as proteoglycans and glycoproteins. Although MMP-2 and MMP-9 are expressed in early wounds (Larjava *et al.*, 1993), they may play a lesser role in later tissue remodeling. MMP-2 is produced constitutively by many cells and only up-regulated by TGF- $\beta$  (Overall *et al.*, 1989), whereas MMP-9 is subject to regulation by a variety of physiologic signals, since its promoter contains two AP-1 regulatory elements (Huhtala *et al.*, 1991). Two other metalloproteinases that do not belong to the aforementioned subgroups are macrophage metalloelastase and a novel transmembrane metalloproteinase (MT1-MMP), which can activate secreted progelatinase-A (proMMP-2) and other proenzymes of the MMP family. However, recent data suggest that this activator of MMPs may not be critical for normal cutaneous-wound healing (Mirastschijski *et al.*, 2004). MMP enzymatic activities are controlled by various inhibitor counterparts called *tissue inhibitors of metalloproteinases* (TIMPs), which are finely regulated during wound repair (Frank *et al.*, 1996).

Cytokines such as TGF- $\beta$ , PDGF, and IL-1 and the extracellular matrix itself clearly play an important role in the modulation of collagenase and TIMP expression *in vivo*. Interestingly, type 1 collagen induces MMP-1 expression through the  $\alpha 2\beta 1$  collagen receptor while suppressing collagen synthesis through the  $\alpha 1\beta 1$  collagen receptor (Langholz *et al.*, 1995). Type 1 collagen also induces expression of  $\alpha 2\beta 1$  receptors (Klein *et al.*, 1991; Xu and Clark, 1996); thus collagen can induce the receptor that signals a collagen degradation-remodeling phenotype. Such dynamic, reciprocal cell-matrix interactions appear to occur generally

during tissue formation and remodeling processes such as morphogenesis, tumor growth, and wound healing, to name a few (Nelson and Bissell, 2006).

Wounds gain only about 20% of their final strength by the third week, during which time fibrillar collagen has accumulated relatively rapidly and has been remodeled by myofibroblast contraction of the wound. Thereafter the rate at which wounds gain tensile strength is slow, reflecting a much slower rate of collagen accumulation. In fact, the gradual gain in tensile strength has less to do with new collagen deposition than further collagen remodeling, with formation of larger collagen bundles and an accumulation of intermolecular cross-links (Bailey *et al.*, 1975). Nevertheless, wounds fail to attain the same breaking strength as uninjured skin. At maximum strength, a scar is only 70% as strong as intact skin (Levenson *et al.*, 1965).

### III. CHRONIC WOUNDS

Acute wounds are those that heal through the routine processes of inflammation, tissue formation, and remodeling, which occur in a timely fashion. As discussed earlier, these processes may overlap temporally. However, the prolonged delay in any of these reparative processes may result in the formation of a chronic wound. Chronic wounds are often associated with underlying pathological conditions that contribute to an impaired healing. Venous leg ulcers and diabetic foot ulcers are common examples of chronic wounds caused or accentuated by an underlying disorder. While the former is induced by insufficient venous flow that results in increased blood pressure in the lower limb and, therefore, increased vascular permeability, the latter is caused by peripheral neuropathy that leads to abnormal load distribution on the foot surface and decreased sensation (Mustoe *et al.*, 2006). Subsequently, these abnormalities cause a loss of tissue viability, suboptimal local tissue permeability, and an elevated and sustained inflammatory response.

### IV. TISSUE-ENGINEERED THERAPY: ESTABLISHED PRACTICE

Initial attempts to speed up wound repair and improve the quality of healing in chronic or burn wounds involved the use of synthetic, composite synthetic, or biological dressings (Bromberg *et al.*, 1965; Robson *et al.*, 1973; Purna and Babu, 2000). Although effective, these dressings did not offer any permanent treatment, since eventually an autograft had to be implanted to achieve complete healing, which is often undesirable due to donor site morbidity.

The advent of tissue-engineered constructs has, however, revolutionized the wound-healing practice (Rosso *et al.*, 2005; Simpson, 2006). These constructs could be classified into two main categories: cellular and acellular. Regardless of whether they are cellular or acellular, the basic building block of these constructs is composed of a biomi-

metic and a scaffolding material. While the biomimetic functions to stimulate cells to perform their physiological functions, the scaffold typically provides a mechanical support for the cells to spread on and to proliferate within, to produce new tissue. However, scaffolds prepared from naturally occurring biopolymers may provide additional biological stimuli to support cell and tissue function (Lutolf and Hubbell, 2005). After implantation, these constructs promote faster healing, resulting in the development of a new tissue that bears a close structural and functional resemblance to the uninjured, host tissue.

These tissue-engineered constructs are typically targeted toward a specific application, i.e., for only epidermal repair, for only dermal repair, or both.

### Engineered Epidermal Constructs

Immediate wound coverage, whether permanent or temporary, is one of the cornerstones of wound management. Engineered epidermal constructs with qualities similar to those of autologous skin have been used to facilitate repair of split-thickness wounds.

Autologous cultured keratinocyte grafts were first used in humans by O'Conner *et al.* (1981). Subsequently there has been extensive experience with cultured epidermal grafts for the treatment of burns as well as other acute and chronic wounds (Butler and Orgill, 2005; Matouskova *et al.*, 2006). Epicel™ (Genzyme Tissue Repair) is an example of an engineered epidermal autograft. The major advantage of this technique is the ability to provide autologous grafts capable of covering large areas, with reasonable cosmetic results. Another significant advantage of autologous grafts is their ability to serve as permanent wound coverage, since the host does not reject them. Disadvantages include the two-to three-week time interval required before sufficient quantities of keratinocytes are available, the need for an invasive and painful procedure to obtain autologous donor cells, and the large costs, estimated at \$13,000 per 1% total body surface area covered (Rue *et al.*, 1993). Furthermore, graft take is widely variable, based on wound status, patient age, general host status, and operator experience (Carsin *et al.*, 2000).

Cultured keratinocyte allografts were developed to help overcome the need for biopsy and separate cultivation for each patient to produce autologous grafts and the long lag period between epidermal harvest and graft product. Cultured epidermal cells from both cadavers and unrelated adult donors have been used for the treatment of burns (Yanaga *et al.*, 2001; Brychta *et al.*, 2002) and chronic leg ulcers (Navratilova *et al.*, 2004; Paquet *et al.*, 2005). Although a previous study showed that allografts made from neonatal foreskin keratinocytes were more responsive to mitogens than those from adult (cadaver) cells (Phillips and Gilchrest, 1991) and, therefore, were the preferred candidate for cultured allografts, a current investigation has revealed that such allografts are also more

immunogenic than the regular cultured skin substitutes (Erdag and Morgan, 2004).

To facilitate mass allograft production and wide availability, cryopreserved allografts have been developed (Navratilova *et al.*, 2004). These frozen constructs give fairly comparable results to fresh allografts (Navratilova *et al.*, 2004). In spite of these advances, the cultured epidermal grafts have failed to produce satisfactory responses. The primary reasons include the lack of mechanical strength and susceptibility to contractures. As an alternative, keratinocyte delivery systems were developed, where the cells were delivered to the injury site via a biodegradable scaffold. For example, laser skin, produced by FIDIA Advanced Biopolymer, Italy, is used to deliver keratinocytes via a chemically modified hyaluronan membrane, which is perforated with micron-sized holes that allow cells to grow to confluence.

### Engineered Dermal Constructs

While the use of cultured keratinocytes to enhance wound healing has met with some success, it lacks a dermal component that, if present, would help prevent wound contraction and provide greater mechanical stability. Allografts (containing dermis) from other sources have been used for many years, although they provide only temporary coverage due to their tendency to induce acute inflammation (Lamme *et al.*, 2002). However, this skin can be chemically treated to remove the antigenic epidermal cellular elements (Alloderm, Life Cell Corporation, Woodlans, TX) and has been used alone or in combination with cultured autologous keratinocytes for closure of various chronic wounds and burns (Gustafson and Kratz, 1999). In spite of these modifications, allogenic grafts, when compared with autologous grafts, have been shown to promote lower percent re-epithelialization and excessive wound contraction (Morimoto *et al.*, 2005). Furthermore, the overall therapeutic outcome of a skin graft depends also on the site from which the cells were isolated (during biopsy) (Wang *et al.*, 2004).

In 1981, Burke *et al.*, developed an acellular composite skin graft made of a collagen-based dermal lattice (containing bovine collagen and chondroitin-6-sulfate) with an outer silicone covering. After placement on the wound, the acellular dermal component recruits the host dermal fibroblasts while undergoing simultaneous degradation. About two to three weeks later, the silicone sheet is removed and covered with an autograft. This composite graft has been used successfully to treat burns and recently received FDA approval for this indication as well as for reconstructive surgery (Integra, Integra Life Sciences Corporation, Plainsboro, NJ) (Dantzer *et al.*, 2003). However, these constructs cannot be used in patients who are allergic to bovine products.

Another rendition of a dermal substitute is Transcyte (Dermagraft-TC) (Advanced Tissue Sciences Inc., La Jolla, CA). This product consists of an inner nylon mesh in which human fibroblasts are embedded, together with an outer

silicone layer to limit evaporation. The fibroblasts are lysed in the final product by freeze-thawing. Prior to that time, the fibroblasts had manufactured collagen, matrix proteins, and cytokines, all of which promote wound healing by the host. Transcyte has been used successfully as a temporary wound coverage after excision of burn wounds (Purdue, 1997; Lukish *et al.*, 2001) and has recently been approved by the FDA for this indication. Dermagraft is a modification of this product in which a biodegradable polyglactin mesh is used instead of the nylon mesh, and the fibroblasts remain viable (Marston, 2004). Use of this dermal substitute has had limited success in the treatment of diabetic foot ulcers (Gentzkow *et al.*, 1996), owing largely to its inability to form stable adhesions with the final epidermal graft (Rennekampff *et al.*, 1996).

### Engineered Skin Substitutes

Full-thickness wounds involve the loss of both the epidermal and dermal layers of the skin. To treat such extensive wounds, Bell *et al.* (1981) first described a bilayered skin composite consisting of a collagen lattice with dermal fibroblasts that was covered with epidermal cells. Modification of this composite consisting of type I bovine collagen and live allogeneic human skin fibroblasts and keratinocytes has been developed (HSE, Apligraf, Organogenesis, Canton, MA). It has been used successfully in surgical wounds (Griffiths *et al.*, 2004) and venous ulcers (Curran and Plosker, 2002). In a large multicenter trial, this product resulted in accelerated healing of chronic nonhealing venous stasis ulcers when compared to standard compressive therapy (Falanga *et al.*, 1998). Both Apligraf (for venous stasis ulcers) and Dermagraft (for diabetic neurotrophic ulcerations) have been available in Canada since 1997 and more recently in the United States. Several other composite skin substitutes combining dermal and epidermal elements have been developed. Composite cultured skin (CCS, Ortec International Inc., New York, NY) is composed of an overlay of stratified neonatal keratinocytes on fibroblasts embedded in distinct layers of bovine type I collagen. This product is currently being evaluated in clinical trials for the treatment of burns and in patients with epidermolysis bullosa. More extensive comparative data of the various biologic dressings have been published elsewhere (Balasubramani *et al.*, 2001).

## V. TISSUE-ENGINEERED THERAPY: NEW APPROACHES

Although the increased healing rates observed with the use of these engineered constructs show promise for the treatment of burns and/or chronic wounds, they have several intrinsic disadvantages that limit their use: (1) The epidermal grafts are very fragile and therefore difficult to handle; (2) it is difficult to quality-control the large-scale production of any cell-populated matrix; and (3) while auto-

grafts require skin biopsy, allografts may experience early rejection. Moreover, these constructs in general are only about 25% efficient, implying that they must be applied on at least four patients before their effect can be seen. These limitations suggest that further improvements be made so that tissue-engineered constructs are not only more effective but also less complex.

A general perception of novel engineering approaches emerges from the foregoing discussions, one that suggests the development of easy-to-handle, user-friendly, cost-effective, acellular, and potent constructs that are based on nonanimal products. Since tissue cells are the primary source of the various ECM molecules that facilitate and synchronize tissue repair, any acellular product must, therefore, be conducive to recruiting the host tissue cells rapidly and inductive to stimulating the invading cells to proliferate, synthesize new ECM, and, if required, differentiate. This design is nonetheless challenging. Cues learned from embryonic, morphogenetic, and wound repair events should be implemented to engineer such tissue constructs.

Over the years, various engineered skin constructs have used collagen as the preferred scaffolding material for cell seeding (Balasubramani *et al.*, 2001). The huge popularity of collagen can be attributed to its abundance in skin and, therefore, its recognition by cell surface receptors, its multiple biological roles during both cutaneous homeostasis and wound repair, and its ability to cross-link and thereby impart mechanical strength to the final construct (Ruszczak, 2003). However, during wound repair, collagen appears only during the later stages, after the invading and proliferating fibroblasts have filled the wound space (Clark, 1996). Therefore, collagen may not be optimal for initial cell migration. Instead, en masse fibroblast migration into the wound clot is accompanied by the synthesis and secretion of hyaluronan, which promotes migration by regulating cell adhesion to the ECM (Chen and Abatangelo, 1999). In fact, hyaluronan also appears coincident with tissue cell migration during embryogenesis and morphogenesis (Toole, 1991).

Hyaluronan is a nonsulfated glycosaminoglycan present in most human tissues. During wound repair, it serves multiple important functions, ranging from regulating inflammation to promoting fibroblast migration and proliferation (Chen and Abatangelo, 1999). Interestingly, hyaluronan has been implicated in the scarless or minimally scarred repair of fetal wounds, perhaps owing to its role in regulating the inflammatory response (Wisniewski and Vilcek, 1997) and collagen deposition (Longaker *et al.*, 1991). Furthermore, similar to synthetic polymers, hyaluronan can be chemically modified to obtain a variety of stable derivatives (Prestwich *et al.*, 1998). Therefore, by offering the advantages of both natural and synthetic materials, hyaluronan promises to be a more suitable scaffolding material for acellular matrices than is collagen. Indeed, chemically modified hyaluronan scaffolds have been successfully used for

various tissue-engineering applications, including wound repair (Campoccia *et al.*, 1998; Kirker *et al.*, 2002).

Our laboratory is developing an acellular, hyaluronan-based matrix to promote dermal repair, where the intent is to provide a reparative dressing or packing material for acute and chronic wounds and, in addition, to facilitate granulation-tissue formation. Since fibroblast migration is the rate-limiting step in granulation-tissue formation (McClain *et al.*, 1996), the matrix must use a biomimetic that supports maximal fibroblast migration. Fibronectin turns out to be a favorable candidate since (1) it appears together with hyaluronan at times of cell migration during embryogenesis, morphogenesis, and wound repair (Toole, 1991; Clark, 1996); (2) fibroblast migration on hyaluronan/fibronectin gels is far greater (approximately fourfold) than on fibrin/fibronectin gels (D. Greiling and R. A. F. Clark, unpublished observation); (3) fibronectin has been shown to be required for fibroblast transmigration from a collagen gel to a fibrin gel (Greiling and Clark, 1997); and (4) fibronectin is absent in chronic wounds, where it is produced normally (Herrick *et al.*, 1996) but eliminated rapidly by the abundant proteases present in chronic wound fluid (Grinnell and Zhu, 1996). Although fibronectin appears to be an ideal biomimetic for use in hyaluronan scaffolds, its stability in the proteolytic environment of chronic wounds is a major concern.

Alternatively, the proteolytically stable arginine-glycine-aspartic acid (RGD) peptide sequence, the smallest cell recognition sequence in the 10th module of type III repeat of fibronectin, can be used to support key cell functions (Pierschbacher and Ruoslahti, 1984). RGD has been widely used to promote cell attachment and spreading in various tissue-engineering applications in general (Hersel *et al.*, 2003) and in wound-healing applications in particular (Pierschbacher *et al.*, 1994). This is perhaps because the RGD sequence is found in a variety of ECM molecules and, therefore, is recognized by the transmembrane integrin receptors of multiple cell types, including dermal and epidermal tissue cells. Our previous study has shown that hyaluronan hydrogels decorated with RGDS (arg-gly-asp-ser) support NIH 3T3 fibroblast functions *in vitro* (Shu *et al.*, 2004) and, when seeded with 3T3 fibroblasts and implanted in nude mice, produce granulation-like tissue in four weeks. Therefore, RGD-modified hyaluronan hydrogels possess great inductive properties. However, these hydrogels neither support optimal dermal fibroblast functions nor demonstrate conductive properties required of any acellular scaffold (Shu *et al.*, 2004).

To impart our acellular matrix with both inductive and conductive properties, we selected, as the biomimetics, three FN functional domains (FNIII<sub>(8-11)</sub>, FNIII<sub>(12-15)</sub>, and FNIII<sub>(12-V-15)</sub>) that are necessary and sufficient for optimal dermal fibroblast migration *in vitro* (Clark *et al.*, 2003). Indeed, our hydrogels have been successful in supporting dermal fibroblast functions *in vitro* and in promoting wound repair *in vivo* (Ghosh *et al.*, 2006). Since these hydrogels can

be formulated at room temperature and physiological pH, they are compatible with both cells and the incorporated biological molecules. In addition, their rapid gelation (<10 min) advocates their possible injectable use. Furthermore, since these hydrogels are derived from components that can easily be produced by bacterial fermentation, they are very cost effective and, unlike animal-derived products, immunocompatible. Another important feature of this tissue-engineered construct is that it can be formulated into myriad physical forms, ranging from hydrogels to electrospun nanofibrous scaffolds (Ji *et al.*, 2006), the latter form mimicking the natural ECM architecture.

With a similar objective, several other groups have also developed “intelligent” scaffolds for tissue repair (Rosso *et al.*, 2005). These approaches commonly employ synthetic materials to build scaffolds, since they allow great flexibility during formulation. To impart bioactivity, these scaffolds contain potent biomimetics that can be recognized by tissue cells. However, as discussed earlier, cell invasion during granulation-tissue formation occurs concurrently with matrix degradation, which can typically be observed when using naturally derived materials. To elicit a similar response in synthetic materials, protease-sensitive sequences are incorporated within the scaffold that are cleaved on contact with the cell-secreted proteolytic enzymes (Lutolf *et al.*, 2003). Therefore, similar to our engineered matrix, these intelligent scaffolds combine the advantages of both natural and synthetic biomaterials to facilitate wound repair.

Traditionally, the structural component of the tissue-engineered constructs has been viewed as providing only a passive mechanical structure. The design proposed here reflects our understanding that cells respond primarily to biological signals. However, recent reports have shown that mechanical forces alone can govern cell and tissue phenotype in ways similar to biological stimuli (Ingber, 2003). Further studies have revealed that cells use an active tactile sensing mechanism to feel and respond to substrate mechanics (Discher *et al.*, 2005; Vogel and Sheetz, 2006). In particular, dermal fibroblasts have been shown to respond to substrate mechanics by regulating levels of gene transcription that eventually lead to differential ECM synthesis and their transformation into myofibroblasts (Chiquet *et al.*, 2003; Hinz, 2006). Since these processes are critical during wound repair, effective tissue-engineering approaches for wound repair would require optimization of both biological and mechanical effectors. In fact, our acellular matrix has been “tuned” to have optimal mechanical properties for skin wound healing.

The acellular tissue-engineered constructs discussed so far utilize scaffolding materials to provide mechanical support for tissue ingrowth and biomimetics to induce key cell functions. The primary goal of these novel approaches is to mimic the attributes of fibrin clot for parenchymal cell migration. However, a fibrin clot and the second provisional matrix composed of fibronectin and hyaluronan is com-

posed not only of a fibrin/fibronectin scaffold and an array of clotting and fibrinolytic enzymes, but also a plethora of growth factors that had been released during platelet aggregation (Mosesson, 2005). Growth factors play a crucial role in the overall healing response, where they function to stimulate cell migration, proliferation, differentiation, and angiogenesis. Furthermore, growth factor deficiency often leads to impaired wound repair (Peters *et al.*, 2005). As a result, several groups have investigated the use of tissue-engineered constructs for local growth factor delivery, where the release of appropriate growth factors produced an increase in angiogenic activity (Richardson *et al.*, 2001; Cai *et al.*, 2005).

It is interesting to note that in spite of the release of growth factors immediately after wounding, there remains a three-day lag before granulation tissue is formed. This suggests that the growth factors may be retained and functional within the clot. This form of solid-state biochemistry may be unconventional, but it is backed by data from recent studies, which have shown that IGF and VEGF bound to specific molecular domains of FN retain or accentuate their

bioactivity (Gui and Murphy, 2001; Wijelath *et al.*, 2002). In fact, studies from our own laboratory have shown that PDGF, when preloaded onto our engineered matrix containing specific domains of FN, retains its activity at the level typically observed in soluble state (K. Ghosh and R. A. F. Clark, unpublished observations). Therefore, by incorporating the appropriate growth factor-binding sequences/domains, tissue-engineered construct can be used as a growth factor repository, causing an increase in local concentration that may ultimately accentuate cell functions.

In conclusion, wound healing is a dynamic and fine-tuned cellular response aimed at reinstating tissue homeostasis after an insult. Vigorous cellular activities observed during wound repair are similar to those occurring during embryogenesis and morphogenesis, which indicates the enormous complexity of this physiological reparative process. That may also explain why, despite over two decades of intense research and development, we have still not identified an ideal therapy. However, novel tissue-engineering approaches are showing tremendous promise and are aiming to push the limits of human expectations of wound therapy.

### I. INTRODUCTION

The engineering of skin tissue has been at the forefront of tissue engineering for many years and has now yielded some of the first medical products to come from tissue engineering. Today, over 200,000 patients have been treated with tissue-engineered skin products. This is the result of work over the last 30 years in the areas of skin cell biology, extracellular matrix biology, collagen scaffolds, polymer scaffolds, and tissue equivalents. The repair of skin using tissue engineering has taken on many forms, from simple to complex. The various strategies are discussed in this chapter, with an emphasis on the biological relevance of each to normal skin structure and function and the healing of wounds.

Skin wounds normally heal by formation of epithelialized scar tissue rather than regeneration of full-thickness skin. Consequently, strategies for the clinical management of wound healing have depended historically on providing a passive cover to the site of the wound while allowing the reparative mechanisms of wound healing: re-epithelialization, remodeling of granulation tissue, and formation of scar tissue. Therapy could do little more than facilitate these little-understood processes. Advances in our understanding of wound healing, wound assessment, the concerted action of several growth factors, the role of the extracellular matrix

in regulating the healing process, and the demonstrated ability of tissue-engineered constructs to promote wound healing highlight the potential for intervening therapeutically in tissue repair by providing lost epithelium, stimulating dermal regeneration, and reconstituting full-thickness skin.

Tissue-engineered skin substitutes are classified into two general categories; cellular-based products, which actively stimulate wound healing; and acellular products, which provide a substrate or covering to facilitate wound healing. Cellular substitutes include autologous epidermal cell sheets (Epicel®, Genzyme Tissue Repair, Cambridge, MA), allogeneic dermal substrates (Dermagraft™, Advanced BioHealing, La Jolla, CA), and human skin equivalent (HSE), composed of both living dermal and epidermal components (Apligraf®,<sup>1</sup> Organogenesis Inc., Canton, MA, Orcel®, Ortec International, New York, NY). Acellular products include Transcyte® (Advanced BioHealing), Integra® Artificial Skin (Integra Life Sciences, Plainsboro, NJ), and Alloderm® (Life-cell Corporation, Branchburg, NJ). These products represent the first of their kind and are the result of basic research in the biology of skin and wound healing and clinical experience with skin grafts, cultured keratinocyte grafts, acellular

collagen matrices, cellular matrices, and cultured composite grafts.

## II. SKIN STRUCTURE AND FUNCTION

The passive and active functions of skin are carried out by specialized cells and structures located in the two main layers of skin, the epidermis and the dermis (Fig. 77.1A). Complex functional relationships between these two anatomic structures of skin maintain the normal properties of skin. Tissue-engineering applications in skin depend on an understanding of the structural components of skin, their spatial organization, and their functional relationships.

### The Epidermis

The skin is a physical barrier between the body and the external environment. The outermost layer of skin, the epidermis, must therefore be tough and impermeable to toxic substances and harmful organisms. It must also control the loss of water from the body to the relatively drier external environment.

The epidermis is composed primarily of keratinocytes, which form a stratified squamous epithelium (Fig. 77.1). Proliferating cells in the basal layer of the epidermis anchor the epidermis to the dermis and replenish the terminally differentiated epithelial cells lost through normal sloughing from the surface of the skin. These basal cells stop proliferating and terminally differentiate as they move from the basal layer through the suprabasal layers to the surface of the epidermis. Keratin filaments and desmosomes contribute physical strength in the living layers and maintain the integrity of the epidermis. The cornified envelopes serve as the bricks and the lipids as mortar.

The most superficial keratinocytes in the epidermis form the stratum corneum, the dead outermost structure that provides the physical barrier of the skin. In the last stages of differentiation, epithelial cells extrude lipids into the intercellular space to form the permeability barrier. The cells break down their nuclei and other organelles and form a highly cross-linked protein envelope immediately beneath their cell membranes. The physically and chemically resilient protein envelope connects to a dense network of intracellular keratin filaments to provide further physical strength to the epidermis.

Additional cells and structures in the epidermis perform specialized functions (Fig. 77.1A). Skin plays a major role in alerting the immune system to potential environmental dangers. The interacting cells in skin comprise a dynamic network capable of sensing a variety of perturbations (trauma, ultraviolet irradiation, toxic chemicals, and pathogenic organisms) in the cutaneous environment and rapidly sending appropriate signals that alert and recruit other branches of the immune system. To restore homeostasis in the skin immune system, the multiple proinflammatory signals generated by skin cells must eventually be counterbalanced by mechanisms capable of promoting resolution of a cutaneous inflammatory response. Dendritic cells of the immune system (Langerhans cells) reside in the epidermis and form a network of dendrites through which they interact with adjacent keratinocytes and nerves (Streilein and Bergstresser, 1984). Melanocytes distribute melanin to keratinocytes in the form of melanosomes. Melanin protects the epidermis and underlying dermis from ultraviolet radiation. Sweat glands help to regulate body temperature through evaporation of sweat secreted onto the skin surface. Sebaceous glands associated with hair follicles secrete sebum, an

oily substance that lubricates and moisturizes hair and epidermis. Hair keeps the body warm in many mammals, although maintaining body temperature is not an important role for hair in humans. Hair follicles, however, are an important source of proliferating keratinocytes during re-epithelialization after severe wounds.

### The Dermis

The dermis underlies the epidermis. The dermis is divided into two regions: the papillary dermis, which lies immediately beneath the epidermis, and the deeper reticular dermis. The reticular dermis is more acellular and has a denser meshwork of thicker collagen and elastic fibers than the papillary dermis. The reticular dermis provides skin with most of its strength, flexibility, and elasticity. Loss of reticular dermis can often lead to excessive scarring and wound contraction.

The dermis provides physical strength and flexibility to skin as well as the connective tissue scaffolding that supports the extensive vasculature, lymphatic system, and nerve bundles. The dermis is relatively acellular, being composed predominantly of an extracellular matrix of interwoven collagen fibrils. Interspersed among the collagen fibrils are elastic fibers, proteoglycans, and glycoproteins.

Fibroblasts, the major cell type of the dermis, produce and maintain most of the extracellular matrix. Endothelial cells line the blood vessels and play a critical role in the skin immune system by controlling the extravasation of leukocytes. Cells of hematopoietic origin in the dermis (e.g., macrophages, lymphocytes) contribute to the surveillance function. A network of nerve fibers extends throughout the dermis, which serves the sensory role in the skin (and, to a more limited extent, a motor function). These nerve fibers also secrete neuropeptides that influence immune and inflammatory responses in skin through their effects on endothelial cells, leukocytes, and keratinocytes (Williams and Kupper, 1996).

### Immunology and the Skin

The first stage in the induction of a primary immune response in skin is the processing of antigen by dendritic cells (Langerhans cells with dermal dendritic cells), the antigen-presenting cells in skin. These cells process antigen and migrate out of the skin to the draining lymph node, where they can recruit and activate T-cells.

The interaction of keratinocytes and fibroblasts with T-cells has important implications for the use of allogeneic cells in tissue engineering. Under normal conditions, keratinocytes and fibroblasts do not express MHC-class II antigens; but they can be induced by interferon- $\gamma$  to express MHC-class II molecules and thereby acquire the ability to present antigen to T-cells. Since the keratinocytes and fibroblasts are deficient in the necessary costimulatory molecules (Nickoloff and Turka, 1994; Phipps *et al.*, 1989), antigen presentation by keratinocytes and fibroblasts does not result

in T-cell activation. Instead, this antigen presentation can result in T-cell nonresponsiveness (Gasparia and Katz, 1988; Bal *et al.*, 1990) or T-cell anergy (Gaspari and Katz, 1991). Therefore, the primary mode of skin rejection is likely mediated via an attack on the vasculature present in a normal skin graft (Poher *et al.*, 1986; Moulon *et al.*, 1999).

Autologous skin grafts avoid issues of immunogenicity, of course, but autologous grafts have significant limitations. Growing graft tissues from biopsy takes several weeks. The donor site creates another wound, and in some patients (e.g., severe-burn patients) there may be no appropriate donor site. Reproducibly making complex human skin equivalent (HSE) constructs to order from autologous cells would be technically difficult, time consuming, and very costly. Therefore, our ability to use allogeneic human cells effectively is a key element in the success of engineered-skin therapies.

### Cell Communication and Regulation in the Skin

Regulation of its own function is an essential role of skin. Epidermis, for example, produces parathyroid hormone-related protein (PTHrP) and plays a role in the regulation of keratinocyte growth and differentiation (Blomme *et al.*, 1998). Keratinocytes produce a large variety of polypeptide growth factors and cytokines, which act as signals between cells, regulate keratinocyte migration and proliferation, for example, and stimulate dermal cells in various ways (e.g., to promote matrix deposition and neovascularization) (McKay and Leigh, 1991; Parenteau *et al.*, 1997). Cytokines produced by keratinocytes are thought to regulate Langerhans cell migration and differentiation (Lappin *et al.*, 1996). Keratinocytes also translate a variety of stimuli into cytokine signals, which are transmitted to the other cells of the skin's immune system. Dermal cells produce and respond to cytokines and growth factors to regulate numerous processes critical to skin function (Williams and Kupper, 1996).

Approaches to dermal repair and regeneration center around control of fibroblast repopulation and collagen biosynthesis to limit scar-tissue formation. One of the keys to improving dermal repair is control, or redirection, of the wound-healing response so that scar tissue does not form. One promising observation is that fetal wounds heal without scarring. TGF- $\beta$ 1, which is not expressed in the fetus, is a potent stimulator of collagen biosynthesis by fibroblasts in the adult and is thought to be an important inducer of scar formation. The matrix composition of the fetal dermis is also significantly different than adult dermis or granulation tissue. Therefore, providing a better matrix environment for dermal cell repopulation may also be key in controlling scar formation.

### The Process of Wound Healing

The immediate tissue response to wounding is clot formation to stop bleeding. Simultaneously, there is a release

of inflammatory cytokines that regulate blood flow to the area, recruit lymphocytes and macrophages to fight infection, and later stimulate angiogenesis and collagen deposition (Williams and Kupper, 1996). These latter processes result in the formation of granulation tissue, a highly vascularized and cellular wound connective tissue. Fibroblasts rich in actin, called *myofibroblasts* (Desmouliere and Gabbiani, 1996), are recruited through the action of factors such as platelet-derived growth factor (PDGF) and transforming growth factor- $\beta$  (TGF- $\beta$ ). Granulation tissue forms in the wound bed, stimulated by factors such as PDGF. This tissue is gradually replaced by scar tissue through the action of the myofibroblasts and factors such as TGF- $\beta$ . Keratinocytes are stimulated to proliferate and to migrate into the wound bed to restore epidermal coverage. From our preclinical observations using both full-thickness HSE and dermal matrices, coverage by the epidermis appears to play a key role in the regulation of the underlying inflammatory response. Providing a noninflammatory living connective tissue implant in the wound defect also appears to be beneficial in directing the granulation response.

Why should living tissue be different in its response? The epidermal and dermal response is regulated by inflammatory cytokines and by autocrine and paracrine factors produced by the dermal fibroblasts and epidermal keratinocytes (Ansel *et al.*, 1990; McKay and Leigh, 1991). These factors regulate growth and differentiation of keratinocytes, proinflammatory reactions, angiogenesis, and deposition of extracellular matrix. Living tissue created through tissue engineering can provide complex temporal control of factor delivery and effect and can be used to provide the needed combination of chemical, structural, and, last but not least, normal cellular elements (Sabolinski *et al.*, 1996).

As this brief description shows, wound healing involves the interaction of many tissue factors and elements. The poor healing response in chronic wounds has been attributed to an imbalance of factors rather than to an insufficiency of any particular factor (Parenteau *et al.*, 1997). However, most, if not all, factor-based approaches have had marginal success. Identification of putative wound-healing factors has led to several attempts to speed wound healing by local application of one or more factors that promote cell attachment and migration. Transforming growth factor- $\beta$  (TGF- $\beta$ ), epidermal growth factor (EGF), vascular endothelial growth factor (VEGF), and platelet-derived growth factor (PDGF) have been candidates for this purpose (McKay and Leigh, 1991; Abraham and Klagsbrun, 1996). Of these, only PDGF has shown efficacy in clinical trials and is approved for clinical use (Regranex<sup>®</sup>, Ortho McNeil, Inc., Raritan, NJ 08869-0602). The arginine-glycine-aspartic acid (RGD) matrix peptide sequence has been found to promote the migration of connective tissue cells and, thus, to stimulate production of a dermal scaffold within the wound bed. This approach has been shown to accelerate healing of sickle-cell leg ulcer and diabetic ulcers (Steed *et al.*, 1995), as compared

with placebo but not when compared with standard care. In addition, complex cell extracts have been used in hopes of providing the appropriate mixture of elements. These include the use of platelet extract to provide primarily platelet-derived growth factor (PDGF) and the use of keratinocyte extracts to provide a complex mixture of elements of rapidly growing keratinocytes—again, with marginal effect, in part due to the complex nature of the wound healing response. In addition, the use of factors is not a sufficient approach, in and of itself, in situations where there is severe or massive loss of skin tissue.

### Impaired Healing and Its Mechanisms

Although there have been many recent advances in the scientific basis for tissue repair, the treatment of chronic wounds and intervening in situations associated with impaired healing have been very challenging problems. A number of reasons account for the impaired healing of chronic wounds, but in general the primary causes have to do with our inability to correct completely their fundamental pathophysiological abnormalities (Falanga, 2005). Preparatory steps before the use of advanced treatments seem to be required, and this preparatory phase may not have received proper attention in the past. For example, failure to prepare the wound properly may lie at the basis of the relative lack of success in the use of topically applied growth factors. This situation is slowly being corrected, but much more needs to be implemented in preparing the wound for the optimal success of advanced wound-healing products and devices. A few years ago, we proposed the notion of “wound bed preparation” as a series of steps to improve the wound before advanced products are used (Falanga, 2001). This concept has gained acceptance.

One of the basic differences between acute and chronic wounds is that in the former the sequence of steps and phases involved (coagulation, inflammation, migration and proliferation, and remodeling) occurs in a very orderly and linear fashion. Such is not the case in chronic wounds, where there is a fundamental asynchrony of the healing process. Within the chronic wound, the various phases of wound repair may be occurring at the same time or not in the appropriate sequence. Wound bed preparation is a way to get the wound to behave more like the acute wound. Often, surgical debridement is all that is required. At other times, treatment of bacterial infection, removal of edema, etc., are essential additional steps (Falanga, 2001).

Bacterial and, in some cases, fungal colonization or infection is a fundamental problem with nonhealing wounds. Some of the causes that foster this colonization and the development of occult infection have already been addressed. These factors include absent epithelium and its barrier properties, the constant wound exudate resulting from bacterial products and inflammation, and poor blood flow and hypoxia (Falanga, 2005). It is well established that wounds have a “bacterial burden” that interferes with

healing. Thus, there is evidence that, regardless of the type of bacteria present, a level greater than or equal to  $10^6$  organisms per gram of tissue is associated with serious healing impairment (Robson *et al.*, 1990). The configuration of the bacterial sheets or colonies is also important. Therefore, there is a great deal of interest at this time in the role played by biofilms, which represent bacterial colonies surrounded by a protective coat of polysaccharides. Biofilms develop mechanisms for antibiotic resistance (Siroky, 2002).

Bioengineered skin constructs may function, at least in part, through the timely and concerted release of stimulatory polypeptides. In this context, one must take into account that simple topical delivery of growth factors into the wound may not be adequate. The nonhealing wound microenvironment can best be described as hostile. Wound exudate in general; the vast abnormalities in the release, activation, and persistence of matrix metalloproteinases (MMPs); and lack of cell adhesion to substrates within the wound bed may all render the growth factors and cytokines unavailable to the healing process. A concept that takes into account these various components has been called the "trap hypothesis" (Falanga and Eaglstein, 1993). It has been hypothesized that nonhealing wounds, particularly in response to bacterial antigens, are characterized by chronic leakage of macromolecules into the wound. These macromolecules may impair healing by trapping cytokines and growth factors. The trap hypothesis suggests that, in spite of achieving adequate levels and even the orchestrated release of these growth factors, the polypeptides are quickly bound and unavailable to the healing process. Common macromolecules that might be involved in trapping include albumin, fibrinogen, and  $\alpha$ -2-macroglobulin. The last is particularly important because it is an established scavenger for growth factors. Fibrinogen can bind to fibronectin, providing a mechanism for the trapping of transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1) (Falanga, 1993).

Moist wound healing has been shown experimentally to accelerate re-epithelialization of acute wounds (Winter, 1962), and these observations have led to a number of moisture-retentive dressings (Ovington, 2001). For chronic wounds, moist wound healing has not been clearly shown to improve epidermal healing, but we do know that moist wound healing helps in the formation of granulation tissue and in relieving pain. Painless debridement, too, is another important property of moisture-retentive dressings (Ovington, 2001). The properties of moist wound healing are important in the field of bioengineered skin constructs, because such constructs lead to increased moisture in the wound bed. Proposed advantages of moist wound healing include retention of cytokines within the wound, facilitation of keratinocyte migration, prevention of bacterial entry, and even poorly understood but favorable electrical gradients. For example, acute wound fluid stimulates the *in vitro* proliferation of fibroblasts, keratinocytes, and endothelial cells. However, fluid and exudate from chronic wounds appear to

have a definite adverse effect on cellular proliferation and to contain excessive amounts of matrix metalloproteinases (MMPs), which can break down key matrix proteins critical to cell migration, such as fibronectin and vitronectin (Falanga, 2005). There is a great deal of information we still need about MMPs and their inappropriate activation in chronic wounds. Some of the information is often contradictory. For example, we do know that MMPs are critical to cell migration. Interstitial collagenase (MMP-1) is a case in point when it comes to keratinocyte migration. However, other enzymes (MMP-2, MMP-9) may prevent or interfere with healing (Falanga, 2005).

An ultimate goal for tissue-engineering constructs would be to offset very fundamental abnormalities that lead to impaired or slow healing. We have been discussing components of impaired healing that, in some way or another, can be approached or at least partially corrected by already available means. However, one important component of impaired healing is ischemia, due to poor arterial supply because of narrowing of blood vessels (i.e., atherosclerosis) or, indirectly, because of pressure on those blood vessels (i.e., pressure ulcers, diabetic neuropathic ulcers). The ischemia, of course, has important consequences for the other components of impaired healing we have discussed, such as bacterial colonization and infection. A challenge is how to use available tissue-engineering products or to modify and develop new ones to correct the problem of ischemia. There are some interesting possibilities that one can use as proof of principle. An example is the role of oxygen tension. Thus, there is no debate over the fact that long-term hypoxia is detrimental to the healing process. This has been readily shown with diabetic ulcers, where low levels of transcutaneous oxygen tension ( $TcPO_2$ ) correlate with inability to heal (Fife *et al.*, 2002). However, and this makes sense even from a teleological point of view, short-term hypoxia actually stimulates healing. It has been shown that hypoxia can increase fibroblast proliferation, fibroblast clonal growth, and the synthesis of several growth factors, including PDGF, transforming growth factor- $\beta$ , and vascular endothelial growth factor (VEGF), among others (Falanga, 2005). Therefore, modulation of the oxygen environment within the wound may offer the possibility of accelerating the healing process. One might even hypothesize that the application of living skin constructs may use up oxygen in the wound bed and that this temporary and relative hypoxia may provide a mechanism of action for these devices.

A very important mechanism for impaired healing is the phenotypic makeup of wound cells. This has critical implications for the use of bioengineered skin construct, in that these constructs may offset cellular phenotypic abnormalities. There is increasing evidence that the resident cells of a chronic wound have developed phenotypic changes that interfere with their response to growth factors and cytokines. Such abnormalities may affect cellular proliferation, locomotion, and the overall capacity to heal (Falanga, 2005).

**FIG. 77.2.** Appearance of Apligraf. (A) Being removed from its pink nutrient agar. (B) Being held just prior to fenestration or meshing. (C) After fenestration with a scalpel. (D) After meshing at a 1.5 : 1 ratio. Copyright V. Falanga, 2006.

Unresponsiveness of chronic-wound fibroblasts to the action of transforming growth factor- $\beta$  and platelet-derived growth factor (PDGF) have been found. Also, the signaling mechanism, which is so critical to the action of cytokines, may be impaired. For example, at least in venous ulcers, there is decreased phosphorylation of Smad2/3 and MAPK p44/42 (Kim *et al.*, 2003).

### III. ENGINEERING SKIN TISSUE

Although the epidermis has an enormous capacity to heal, there are situations in which it is necessary to replace large areas of epidermis or in which normal regeneration is deficient. The dermis has very little capacity to regenerate. The scar tissue that forms in the absence of dermis lacks the elasticity, flexibility, and strength of normal dermis. Consequently, scar tissue limits movement, causes pain, and is cosmetically undesirable. Engineered tissues that not only close wounds but also stimulate the regeneration of dermis would provide a significant benefit in human wound healing.

An engineered skin graft should incorporate as many of these factors as possible: (1) the extracellular matrix; (2) dermal fibroblasts; (3) the epidermis; and (4) a naturally occurring semipermeable membrane, the stratum corneum (Fig. 77.2). These components may act alone, but, more importantly, they act synergistically as part of a fully integrated tissue to protect the underlying tissues of a wound bed and to direct healing of the wound (Sabolinski *et al.*, 1996). Dermis containing fibroblasts may be necessary for the maintenance of the epidermal cell population. In turn, the epidermis is necessary for the formation of the so-called

neodermis, in the absence of a dermal layer and can dramatically influence underlying connective-tissue response. The formation of the epidermal barrier also likely influences these processes through control of water loss and its influence on epidermal physiology (Parenteau *et al.*, 1996).

### Design Considerations

Tissue engineering has not focused on regenerating certain skin structures, such as hair follicles and sebaceous glands, whose loss is clinically less significant than the loss of dermis and epidermis needed to cover and protect the underlying tissues. There is some preliminary evidence that sebaceous glands may be possible in the HSE (Wilkins *et al.*, 1994), although the development of functioning adnexal structures is likely to be years away. There has also been little need extraneously to stimulate regeneration of other dermal components (e.g., blood vessels and cells of the immune system) through tissue-engineering methods because these components have the ability to repopulate quickly and to normalize the area of a wound. Langerhans cells, for example, have been shown to migrate and repopulate effectively within months (Desmouliere and Gabbiani, 1996). Control of vascularization is dependent on the makeup of the extracellular matrix and the degree of inflammation present in the wound. Whether modification of vascularization through the use of exogenous factors will be of additional benefit for certain wounds remains to be determined. While pigmentation is not critical for wound healing, clinical studies using Apligraf HSE, which lacks melanocytes, has shown repigmentation of the grafted areas through repopulation of the area with host melanocytes, resulting in normal

**FIG. 77.3.** Histological appearance of Apligraf (A) compared to normal human skin (B). A well-defined epidermal and dermal layer is observed in both. Copyright V. Falanga, 2006.

skin color for each individual. The constructs should have sufficient mechanical strength to allow for clinical manipulations (Fig. 77.3). The approach tissue engineering has taken has been to focus primarily on providing or imitating structural and biological characteristics of dermis, epidermis, or both.

The key features to be replicated in an engineered skin construct are:

1. A dermal or mesenchymal element capable of aiding appropriate dermal repair and epidermal support
2. An epidermis capable of easily achieving biologic wound closure
3. An epidermis capable of rapid re-establishment of barrier properties
4. A permissive milieu for the components of the immune system, nervous system, and vasculature
5. A tissue capable of achieving normalization of structure and additional function, such as reduction of long-term scarring and re-establishment of pigmentation
6. Active cellular component(s) capable of responding to different wound types and conditions
7. Sufficient mechanical strength to allow for clinical manipulation
8. Persistence of cells in the wound for multiple weeks to stimulate the healing process through delivery of cytokines and matrix proteins

### Commercial Considerations

Tissue engineering is a unique and emerging industry. Engineered skin constructs, by virtue of being the first products commercialized, have been at the forefront, blazing trails in science, industry, and regulations. In recent years, more attention has been given to the subject of commercialization. In 2004, Lysaght and Hazlehurst published a review of tissue-engineering companies. The review highlighted that while the number of companies had increased from 2000 to 2002, annual spending and the number of full-time employees had declined. In addition, it showed a trend away from U.S.-based companies. Lysaght concluded that the industry is viable, characterized by small-scale companies heavily technology based, which is indicative of an industry

in transition from small-scale discovery-and-research companies to larger, more well-established profitable companies. The transition from start-up to well-established profitable companies is dependent on having a viable business model.

Apligraf, Dermagraft, and OrCel initially struggled with the task of commercializing their technologies. Significant restructuring of business models has occurred, with varying success. Dermagraft had been removed from the market by Smith & Nephew and reintroduced by Advanced BioHealing. In the case of Apligraf, Organogenesis was restructured. Much of the restructuring was centered on understanding the cost of manufacturing and working to reduce those costs while increasing efficiency and maintaining high quality. In addition to the work done to reduce costs and increase efficiencies, the company, Organogenesis, incorporated the functions formerly performed by their marketing partner: sales and marketing, customer service, reimbursement, and distribution. Having all of these functions in the same company is proving to be of benefit by allowing for a more integrated strategic company. As of 2006, Apligraf had been applied to over 130,000 patients.

There are many components to a business model. In general, the intent is to understand the relationship between the cost of getting the product to market and the revenues expected to be realized once the product is commercialized. If the cost of development, clinical testing, and manufacture of the product is much higher than what you can expect to receive in revenue after product launch, then the business model should be reconsidered. This may seem a simple principle, but in practice it can be difficult to capture the proper data for this analysis and properly anticipate changes in markets as the product evolves. It can take years to get to the point where you are ready to launch a product, making it necessary to continually revisit and adjust the business model accordingly. Alternate sources of revenue, different or additional clinical indications for the product, and modifications to the manufacturing process to reduce costs are just some of the components that could be reexamined in the business model. The costs associated with effective manufacturing have a major impact on the business model

and are one element that can be considered very early in the product development life cycle. Understanding the unique skill sets required to market and sell these cell-based products is another area that requires significant consideration early in the process. However, we will not discuss this aspect of a business plan because it goes beyond the scope of this chapter.

Early in the product concept stage, consideration should be given to the design of the manufacturing process. Elements such as critical process parameters, quality control assays, production components and materials, process equipment, production facility requirements, and distribution methods need to be developed in some detail. From this design, the cost of manufacturing and strategies for scale-up and automation can be developed. The requirements for the manufacturing facility are directly related to the design of the manufacturing process. For example, a highly manual process requires a large, highly specialized staff with a relatively large manufacturing floor space, whereas a more automated process requires a less specialized staff and potentially less manufacturing floor space. An open process requires tighter environmental controls; developing a closed process reduces the need for tight environmental controls, thus reducing facility costs. All of these elements impact the cost of manufacturing and the potential for scale-up. These pioneering lessons learned in scale-up apply to the broader field of tissue engineering.

Through this process, strategies for scale-up and automation can be evaluated and planned for. More importantly, process components that will pose significant barriers to scale-up or automation can be identified and addressed while the product is still in research and development. This is critical when you consider that the further along in the development process, the more committed you become to the process design. The cost of making a significant process change increases the closer you get to manufacturing and becomes exponentially more expensive and time consuming post-product launch. Along these same lines, materials used in the process that are ill-defined, cell-based, single sources or of limited supply can contribute to a manufacturing process that is difficult to scale-up and control from a quality standpoint. These factors will influence the yield from the manufacturing process or, stated another way, the scrap rate for the product. High scrap rates increase manufacturing costs and create issues for inventory management.

Increasingly, agency's like the U.S. Medicaid and Medicare program as well as foreign government reimbursement agencies are requiring convincing data on the value and effectiveness of therapy as compared to standard of care or competing technologies (Archer and Williams 2005). The Center for Devices at the the FDA (21 CFR 820.30) requires products to be developed following design control procedures. Cell-based HSEs are classified and regulated as medical devices, though the trend at FDA is to regulate

cell-based products as biologics. These design guidelines are in place to ensure that products that are developed will be safe and effective and have a sound business model. Establishing a design control system early will help refine the business model throughout the development life cycle. Not only is design control a regulatory requirement, but it makes good business sense.

There are critical issues and barriers to commercialization all along the continuum from product concept, through development, clinical evaluation, FDA approval, product launch, and reimbursement, to steady-state manufacturing. Developing a dynamic business model that takes all of these factors into account will increase the likelihood for a profit-generating product. Good science alone is not enough to ensure success. Understanding the challenges and working to incorporate process designs that are forward-looking, will be amenable to scale-up, address regulatory hurdles, and are supported by a viable business model are necessary for the industry to grow.

## IV. EPIDERMAL REGENERATION

Re-epithelialization of the wound is a paramount concern. Without epithelial coverage, no defense exists against contamination of the exposed underlying tissue or loss of fluid. The approaches to re-establishing epidermis are numerous, ranging from the use of cell suspensions to full-thickness skin equivalents possessing a differentiated epidermis. Silicone membranes have been used as temporary coverings in conjunction with dermal templates (Heimbach *et al.*, 1988). Regardless of approach, living epidermal keratinocytes are necessary to achieve permanent, biologic wound closure.

Green *et al.* (Phillips *et al.*, 1989; Green *et al.*, 1979) developed techniques for growing human epidermal keratinocytes from small patient-biopsy samples using coculture methods (Rheinwald and Green, 1975). The mouse 3T3 fibroblast feeder cell system allows substantial expansion of epidermal keratinocytes and can be used to generate enough thin, multilayered epidermal sheets to resurface the body of a severely burned patient (Gallico *et al.*, 1984). Once transplanted, the epidermal sheets quickly form epidermis and re-establish epidermal coverage. With time, the cultured epithelial autograft (CEA) stimulates formation of new connective tissue (*neodermis*) immediately beneath the epidermis, but scarring and wound contraction remain significant problems. Studies have shown that grafting of CEA onto pregrafted cadaver dermis greatly improves graft take (Odessey, 1992). Cultured epithelial autografts (Epicel) have been available since the late 1980s.

## V. DERMAL REPLACEMENT

Human cadaver allograft skin has been used when autologous skin grafts are not possible. Problems associated with human cadaver allografts include the possibility of an immune rejection reaction, potential for infection, and

problems of supply and variability in the quality of the material. Decellularized dermal tissue has also been used in an attempt to recapitulate as much of the normal architecture as possible while providing a natural scaffold for reepithelialization (Middelkoop *et al.*, 1995; Langdon *et al.*, 1988). Cadaver allograft dermis can be processed to make an immunologically inert, acellular dermal matrix with an intact basement membrane to aid the take and healing of ultrathin autografts (AlloDerm) (Lattari *et al.*, 1997). Currently, only the upper papillary layer of dermis is used clinically (AlloDerm). One limitation to this approach is that deep dermis and the more superficial papillary layer differ in architecture. The deep reticular dermis is needed to prevent wound contraction. Work is being done to develop a similar type of implant derived from deeper reticular dermis. Providing an appropriate scaffold for deep dermal repair remains a challenge for groups investigating native as well as synthetic matrices.

Tissue engineers have investigated the possibility of redirecting granulation-tissue formation through the use of scaffolds and living cells. In one of the earliest tissue-engineering approaches to improving dermal healing, Yannas *et al.* (1982) designed a collagen–glycosaminoglycan sponge to serve as a scaffold or template for dermal extracellular matrix. The goal was to promote fibroblast repopulation in a controlled way that would decrease scarring and wound contraction. A commercial version of this material composed of bovine collagen and chondroitin sulfate with a silicone membrane covering (Integra™, Integra Life Sciences, Plainsboro, NJ) is currently approved for use in burns (Heimbach *et al.*, 1988). The dermal layer is slowly resorbed, and the silicone membrane is eventually removed, to be replaced by a thin autograft.

Several variations on the collagen sponge have been studied. Efforts have been made to improve fibroblast infiltration and collagen persistence by collagen cross-linking (Middelkoop *et al.*, 1995; Cooper *et al.*, 1996), by inclusion of other matrix proteins (Hansbrough *et al.*, 1989; Ansel *et al.*, 1990; deVries *et al.*, 1993) and hyaluronic acid (Cooper *et al.*, 1996), and by modifying the porosity of the scaffold (Hansbrough *et al.*, 1989; Yannas *et al.*, 1989).

Although matrix scaffolds have shown some improvement in scar morphology, no acellular matrix has yet been shown to lead to true dermal regeneration. This may be due in part to limits in cell repopulation, the type of fibroblast repopulating the graft, and control of the inflammatory and remodeling processes (i.e., the ability of the cells to degrade old matrix while synthesizing new matrix). The inflammatory response must be controlled in dermal repair in order to avoid the formation of scar tissue. Therefore, dermal scaffolds must not be inflammatory and must not stimulate a foreign-body reaction. This has been a problem in the past for some glutaraldehyde cross-linked collagen substrates (deVries *et al.*, 1993). The ability of the matrix to persist long enough to redirect tissue formation must be balanced with

the effects of the matrix on inflammatory processes. One way to achieve this is to form a biological tissue that is recognized as living tissue, not a foreign substance.

There have been advances in the design of artificially grown dermal tissues using human neonatal fibroblasts grown on rectangular sheets of biodegradable mesh (Dermagraft). The fibroblasts propagate among the degrading fibers, producing extracellular matrix in the interstices of the mesh. A related product was a nonviable temporary covering for burns. In this case a nylon mesh coated with porcine collagen and layered with a nonpermeable silicone membrane (Biobrane®, Dow Hickam, Sugarland, TX) serves as a platform for deposition of human matrix proteins and associated factors by the human dermal fibroblasts (Transcyte, Dermagraft-TC). The material was then frozen to preserve the matrix and factors produced by the fibroblasts. The temporary covering would be removed prior to autografting.

## VI. COMPOSITE SKIN GRAFTS

Human skin autograft has been the gold standard for resurfacing the body and closing wounds that are difficult to heal. Cultured epidermal grafts are more likely to take when the dermal bed is relatively intact, probably because dermal factors influence epithelial migration, differentiation, attachment, and growth (Clark, 1993; Greiling and Clark, 1997). The epidermis and dermis act synergistically to maintain homeostasis (Parenteau *et al.*, 1997).

Boyce *et al.* have modified the approach first proposed by Yannas *et al.* to form a bilayered composite skin made using a modified collagen–glycosaminoglycan substrate seeded with fibroblasts and overlaid with epidermal keratinocytes (Boyce and Hansbrough, 1988). An autologous form of this composite skin construct has been used to treat severe burns, with some success (Hansbrough *et al.*, 1989). An allogeneic form of the construct showed improved healing in a pilot study in chronic wounds (Boyce *et al.*, 1995). A similar technology has been studied in the treatment of patients with genetic blistering diseases.

One of the first attempts to replicate a full-thickness skin graft was by Bell *et al.* (1981), who described a bilayered skin equivalent. The dermal component consisted of a lattice of type I collagen contracted by tractional forces of rat dermal fibroblasts trapped within the gelled collagen. This contracted lattice was then used alone or as a substrate for rat epidermal keratinocytes. They demonstrated the ability of these primitive skin equivalents to take as a skin graft in rats. This technology has now advanced to enable the production of large amounts of human Apligraf HSE from a single donor (Wilkins *et al.*, 1994). Using methods of organotypic culture that provides a three-dimensional culture environment permissive for proper tissue differentiation, the resulting HSE develops many of the structural, biochemical, and functional properties of human skin (Boyce and Hansbrough, 1988).

The process for formation of HSE has been covered in detail many times (Boyce and Hansbrough, 1988; Wilkins *et al.*, 1994) and will not be detailed here. However, there are points to be made about the approach to these procedures. The culture of HSE proceeds best with minimal intervention. Normal cell populations seem to have an intrinsic ability to re-express their differentiated program *in vitro*. A medium that supplies adequate amounts of nutrients, lipid precursors, vitamins, and minerals may be all that is required (Wilkins *et al.*, 1994). Another element is the environmental stimulus provided by culture at the air-liquid interface, which promotes differentiation and formation of the epidermal barrier (Boyce and Hansbrough, 1988).

The immunology of allogeneic tissue-engineered skin grafts is poorly understood. Inconsistencies in the literature are due, in part, to the complexity of biological and immunologic factors, which determine the ability of a graft to take and to persist over time. Among the properties that determine the immunogenicity of an engineered allogeneic graft are the purity of cell populations, the antigen-presenting capabilities of graft cells, and the vascularity of the graft.

The purity of cell populations is critical. Differences in cell purity between laboratories could contribute to the conflicting results found in murine and human studies (Hefton *et al.*, 1983; Thivolet *et al.*, 1986; Cairns *et al.*, 1993). Both culture condition and passage number affects the purity of cell populations. Very early passages of keratinocyte and fibroblast cultures might be expected to contain contaminating cell populations.

The antigen-presenting capabilities of keratinocytes and fibroblasts are also critical to determining the immunogenicity of the HSE grafts. Fibroblasts and keratinocytes are not professional antigen-presenting cells and fail to stimulate the proliferation of allogeneic T-cells (Nickoloff *et al.*, 1986; Niederwieser *et al.*, 1988; Gaspari and Katz, 1991). Both of these cell populations inherently do not express HLA class II molecules or costimulatory molecules such as B7-1 (Nickoloff *et al.*, 1993). The inability of keratinocytes and fibroblasts to induce proliferation of allogeneic T-cells is due primarily to the lack of expression of costimulatory molecules, even though aberrant antigen processing and invariant chain expression may also contribute (Nickoloff and Turka, 1994).

The ability to utilize allogeneic cells rather than autologous cells as in CEA therapy enables the reproducible manufacture of consistent Apligraf HSE (Wilkins *et al.*, 1994). The inability of epidermal keratinocytes and dermal fibroblasts to stimulate a T-cell response, discussed earlier, permits their use in allogeneic applications. Studies in athymic mice indicate that the use of a differentiated tissue such as the Apligraf HSE also beneficially affects its ability to engraft successfully (Nolte *et al.*, 1994; Parenteau *et al.*, 1996). Severe combined immunodeficient mice (SCID), who lack a functioning immune system, can be successfully transplanted with a functioning human immune system

without risk of rejection. SCID mice transplanted with human leukocytes were used as an *in vivo* model to assess the immunogenicity of allogeneic skin grafts (Moulon *et al.*, 1999). In these studies, human skin was rejected, while allogeneic tissue-engineered skin graft survival was 100%.

## VII. BIOENGINEERED SKIN: FDA-APPROVED INDICATIONS

The rather formidable obstacles to healing present in chronic wounds have made it difficult for the simple topical application of growth factors and cytokines to have a successful outcome. It can be argued that tissue engineering, particularly with living cells, has an advantage, in that cells may be capable of responding to the microenvironment and thus behave in a “smart” way, from an engineering point of view. Because of these considerations, cell therapy with bioengineered skin has been tested in difficult-to-heal wounds. Figures 77.2 and 77.3 show Apligraf before and after meshing and fenestration as well as its histological appearance. Venous and neuropathic diabetic ulcers have received the greatest attention. Two main types of living bioengineered skin have been proven effective in diabetic neuropathic foot ulcers and have received regulatory approval from the FDA. In a randomized 12-week trial of 208 patients with neuropathic ulcers, Apligraf led to complete wound closure in 56% of patients, compared to 38% in the control group (off-loading alone) (Veves *et al.*, 2001). The Kaplan–Meier median time to complete wound closure was 65 days for Apligraf and 90 days for control. Figure 77.4 shows a diabetic neuropathic foot ulcer successfully treated with Apligraf. It is important to note, as detailed in the FDA-approved indication, that patients in the active arm of that study showed decreased incidence of osteomyelitis and amputation. These results on key complications of diabetic foot ulcers may have been due to faster healing. Another living cell product, Dermagraft, was shown in a 12-week randomized study to heal neuropathic foot ulcers, with an incidence of closure of 30% and 18% for the active and control arms, respectively (Marston *et al.*, 2003).

In addition to its indication for diabetic ulcers, Apligraf also remains the only approved tissue-engineered product for venous ulcers. In a pivotal multicenter randomized study of 293 patients with venous leg ulcers, Apligraf was more effective than leg compression alone (control) in the percentage of patients who healed by six months (63% vs. 49%) (Falanga *et al.*, 1998). That study also showed that Apligraf healed ulcers that were larger and deeper than those in the control group. No evidence of sensitization was observed with the bioengineered skin product. Interestingly, a subsequent reanalysis of the data from this pivotal trial, limited to 120 patients with venous ulcers longer than one year in duration, showed that Apligraf owed its overall effectiveness to these hard-to-heal ulcers. In this subgroup

**FIG. 77.4.** Diabetic neuropathic foot ulcer successfully treated with Apligraf. **(A)** Just after surgical debridement to remove the necrotic wound bed and surrounding callus. **(B)** Wound covered with meshed Apligraf. **(C)** Appearance of construct a week later. **(D)** At three weeks. **(E)** Complete wound closure at five weeks. Copyright V. Falanga, 2006.

of the study population, Apligraf healed 47% of patients, compared to 19% in the control group (Falanga and Sabolinski, 1999). This observation, taken together with the mechanisms underlying impaired healing, suggests that cell therapy might have a greater effect when there are more substantial abnormalities leading to a prolonged failure to heal.

### Apligraf: Off-Label Uses

Off-label use is the practice of using products for purposes not approved by the FDA. Physicians can prescribe and use products as they see fit because they are not regulated and are recognized as experts in their fields. It is illegal for the parent companies of the products to promote off-label use. However, data generated by off-label use can be very valuable and lead to new insights into how the products function and, potentially, clinical trials for new indications.

From both a therapeutic and purely scientific standpoint, of critical importance in the context of the clinical trials just detailed is that, for the very first time, one has been able to show a beneficial effect of tissue-engineered products in situations of impaired healing. Understandably, clinicians have also used Apligraf off-label to accelerate healing in wounds not due to venous disease or diabetes (Shen and Falanga, 2000). Wounds that have been treated off-label with Apligraf include acute wounds after extensive skin surgery, donor sites after split-thickness skin harvesting, traumatic wounds, burns, inflammatory ulcers such as pyoderma gangrenosum and vasculitis, scleroderma digital ulcers, wounds after keloid removal, genetic conditions

such as epidermolysis bullosa, and a variety of situations that defy proper diagnosis because of their complexity. In these cases, bioengineered-skin treatment with Apligraf seems to offer a viable alternative to stimulate wound healing and relieve unacceptable pain and suffering. Some examples suffice. Pyoderma gangrenosum is an inflammatory ulcer often associated with rheumatoid arthritis, inflammatory bowel disease, and IgA gammopathy, among other predisposing factors. A peculiar feature of pyoderma gangrenosum is that it worsens with surgical manipulation and even develops at distant sites that are traumatized; thus, autologous grafting is a contraindication and bioengineered skin is an attractive therapeutic modality (DeImus *et al.*, 2001). In a patient with multiple myeloma undergoing conditioning for bone marrow transplantation, extravasation of the chemotherapeutic drug adriamycin occurred into his chest and created a very large and deep painful wound. Apligraf proved to play a major role in healing the full-thickness wound (Fig. 77.5) and led to a dramatic relief in pain. Pressure ulcers, too, have been treated with Apligraf. This is of particular interest because, based on the engineering aspects of the construct, one would have expected that very deep wounds with loss of a great deal of tissue would not respond to Apligraf. Yet it appears that in such cases Apligraf is able to stimulate tissue regrowth in deep ulcers and not just re-epithelialization from the edges of the wound (Fig. 77.6). Scleroderma digital ulcers are ischemic in nature and have no known accepted treatment. Yet Apligraf appears promising in those wounds (Fig. 77.7). There is no evidence that Apligraf stimulates malignancy within the wound bed, possibly due to its stimulatory action. An interesting case in

**FIG. 77.5.** Systemic sclerosis (scleroderma) digital ulcer treated with Apligraf. (A) Baseline ulcer with fibrinous wound bed. (B) Wound covered with meshed Apligraf. (C) Wound closure four weeks later. Copyright V. Falanga, 2006.

point is shown in Fig. 77.8, where multiple and ulcerated basal cell carcinomas in the foot of a patient with the hereditary form of basal cell nevus syndrome were treated with Apligraf.

The clinical results from the off-label use of Apligraf to treat epidermolysis bullosa, or EB, have prompted the initiation of clinical trials. Epidermolysis bullosa is a genetic skin disorder characterized by blistering of the skin and mucosae following mild mechanical trauma (Falabella *et al.*, 2000). Falabella *et al.* performed an open-label uncontrolled study of 15 patients with EB treated with Apligraf. The conclusion was that Apligraf induced rapid healing; the wounds

remained healed for some weeks, and there was no acute rejection reaction or other adverse effects related to the treatment. Currently there is no specific treatment for EB, and the nature of the condition is that these wounds tend to heal slowly and in some instances fail to heal, becoming chronic wounds. Most wound treatment is supportive, such as sterile wound dressings and analgesics. As a result of the work done by this group as well as by others, Organogenesis has partnered with the epidermolysis bullosa patient advocate group (DebRA) to launch jointly a randomized, controlled, multicenter trial to offer evidence that Apligraf is efficacious in the treatment of EB.

## VIII. MECHANISMS OF ACTION OF BIOENGINEERED SKIN

The mechanisms of action by which bioengineered skin, in particular Apligraf, is effective in accelerating healing remain unknown. It has been stated that the delivery of living cells is associated with the release of growth factors

and cytokines (Mansbridge *et al.*, 1998; Falanga *et al.*, 2003). Indeed, we have previously shown that, when wounded *in vitro*, Apligraf undergoes a staged expression of inflammatory cytokines and, later, growth factors, which is very much reminiscent of the normal process of wound healing. A host of cytokines are produced by Apligraf, and there is evidence

**FIG. 77.9.** Patient with a hereditary form of basal cell carcinomas (the basal cell nevus syndrome). His entire body was covered with these skin cancers. **(A)** Nonoperative ulcerated basal cell carcinomas (proven histologically) on the lateral side of the foot. **(B)** Ulcerated cancers treated with Apligraf. **(C)** Appearance of same site several months after Apligraf application and without obvious clinical evidence of extension of the skin cancers. that its epidermal and dermal components work in concert to produce these mediators that would not normally be detected with the epidermal and dermal component alone (Falanga *et al.*, 2003). In this regard, it is notable that there is a close interaction between Apligraf and the wound and that hyaluronic acid is deposited in large amounts by both the construct and the wound. Hyaluronic acid deposition is a hallmark of fetal wound healing, and it is possible that the Apligraf promotes a more fetal-like stimulation of the wound-healing process (Badiavas *et al.*, 2002). Another interesting property of Apligraf, which is due to its unique bilayered configuration, is that it undergoes epiboly *in vitro* (Nahm *et al.*, 2004). This ability to migrate over its own dermis suggests a very viable epidermal component, capable of allowing the construct to heal itself after injury (Falanga *et al.*, 2003).

The available evidence indicates that the cells from these allogeneic constructs, including Apligraf, do not persist in wounds (Phillips *et al.*, 2002; Griffiths *et al.*, 2004). This has been shown in acute wounds as well as in venous ulcers, where the donor allogeneic cells do not survive for more than four to six weeks, based on HLA typing using PCR. Thus, there is strong evidence that true engraftment or prolonged persistence of cells from these allogeneic constructs does not occur. The survival of cells from Apligraf may be longer in the neonatal period or in children, as suggested by reports that Apligraf cells may be detectable many more weeks or even months when the construct is applied in the wounds of young patients with epidermolysis bullosa, a condition characterized by a variety of genetic defects in molecules responsible for anchoring the epidermis to the dermis (i.e., laminin 5, type VII collagen) (Fivenson *et al.*, 2003). Still, in spite of a lack of longevity of the construct, the clinical trial results indicate that even a few days or weeks of exposure of the wound to Apligraf has beneficial effects. Possible mechanisms include a more orderly and

orchestrated release of cytokines, deposition of extracellular matrix material important for early migration of mesenchymal cells and keratinocytes, and even the attraction of progenitor or stem cells from deep in the tissue or from the circulation (Falanga, 2005). For example, myoblast-like cells have been noted deep in the subcutaneous tissue.

Although it is tempting to think of Apligraf as a graft, available evidence indicates that this construct behaves like cell therapy. We have already discussed the issue of allogeneic cell longevity, which in itself speaks against the idea of Apligraf's being a graft. Moreover, there is no evidence that wound bed blood vessels grow into Apligraf, as is commonly observed with autologous grafts. Perhaps most telling is the fact that, uniformly, Apligraf seems to stimulate the edges of the wound to migrate toward the center. This "edge effect," which has also been reported with the application of living keratinocyte sheets, is the predominant observation with successful Apligraf treatment, although a variety of clinical presentations are seen that, at least at times, suggest that the construct is still present in the wound bed (Fig. 77.9). The edge effect strongly suggests that Apligraf does not act as a tissue replacement but, rather, as cell therapy. Indeed, the rate at which the edges of a wound migrate toward the center has been used to determine whether eventual wound closure will occur. The data appear to indicate that an advancement of the edge of more than 0.7 mm per week is about 80% sensitive and specific for ultimate wound closure. Apligraf seems to increase this healing rate, up to approximately 1.5 mm per week (Falanga and Sabolinski, 2000).

An interesting issue with regard to Apligraf, other than cytokine release and matrix deposition (but perhaps related to it), is its physical configuration and timing of contact with the wound bed. For example, we have shown that contact of Apligraf with the wound must ideally be for at least two weeks for a successful outcome to occur (Saap *et al.*, 2004).

**FIG. 77.10.** Different clinical appearances of wounds after Apligraf application. **(A)** Diabetic foot ulcer, with white center representing Apligraf three weeks after application. **(B)** Venous ulcer still showing an Apligraf-like material six weeks later. **(C)** Pyoderma gangrenosum only two weeks after Apligraf application and with thin layer of epidermis completely covering the wound bed. **(D)** Classical “edge effect” (arrow) at the margins of a venous ulcer treated with Apligraf. The yellow material at the bottom of the pictures represents what is left of meshed Apligraf applied three weeks earlier. Copyright V. Falanga, 2006.

Another observation has been that the migrating tongue of the wound edge seems to “walk” over the Apligraf, even when the latter has the appearance of being broken down or certainly not intact (Fig. 77.10). Of most interest, defying the idea of architectural tissue replacement, is the observation that Apligraf is effective even when placed in the center of the wound, approximately 1 cm away from the wound edges, and that the beneficial clinical outcome occurs even when the construct is placed over the wound with its dermal side up (Fig. 77.11). Taken together, these observations and considerations lead to the notion that Apligraf acts as a tissue unit on its own, perhaps stimulated by the wound environment or by the meshing and fenestration of the construct that are usually done to allow for wound fluid to escape and to expand the coverage ability of the construct (Brem *et al.*, 2004; Cavorsi *et al.*, In press).

Cell therapy appears to be the primary mechanism, but the work done with epidermolysis bullosa patients suggests additional or alternative mechanisms. As discussed previously, Apligraf has been used off-label for the treatment of epidermolysis bullosa, or EB. Inherited EB is a heterogeneous group of rare genetic skin diseases. The diseases are characterized by blistering of the skin and mucosae following mild mechanical trauma; most forms result in a lifetime of blister and wound formation. The blistering is a result of the mechanical fragility of the basal cells of the epidermis, and this fragility has been linked to mutation in the keratin K5 and K14 genes (Falabella *et al.*, 1999). Although some forms of EB are associated with normal longevity, several severe forms have significant morbidity and increased mortality, as either a direct or an indirect result of the disease

**FIG. 77.11.** Histological appearance and intimate interaction of Apligraf and an ulcer due to pyoderma gangrenosum several days after construct application. The edges of the wound are extending a thin layer of epidermis (single arrows) over the remnant of the construct (double arrows). It would appear that the native keratinocytes are using Apligraf as a substrate on which to migrate. Copyright V. Falanga, 2006.

(Falabella *et al.*, 1999, 2000). The work done with these patients has produced dramatic clinical results, where patients experience more rapid healing and a reduction in the frequency of blister formation in the treated areas as well as greater function and range of motion when used to

**FIG. 77.12.** Unusual applications of Apligraf in two patients with venous ulcers. **(A)** Apligraf applied in the center, about 1 cm away from the wound edge. **(B)** Almost-complete wound closure a week later. Apligraf is still visible in the center of the wound. **(C)** Apligraf applied in the normal way (epidermal side up) or with dermal side up. **(D)** Regardless of Apligraf orientation, there is definite evidence of reepithelialization from the wound edges. treat severe mitten deformity (Fivenson *et al.*, 2003a, 2003b; Falabella *et al.*, 2000).

With EB patients, the decrease in reblistering in treated sites as compared to untreated sites suggests that the patient's skin "learns" from the allogeneic tissue. In the EB patients, donor DNA has been found up to six months postoperatively (Fivenson *et al.*, 2003a, 2003b), in contrast to venous leg ulcers, where donor DNA was detected one month postoperatively but not detected at two months (Phillips *et al.*, 2002). The DNA analysis showed specific donor DNA sequences (HLADQB10201 and Short Tandem Repeat) at the treated sites six months after receiving Apligraf (Graftskin). The presence of this DNA is significant because it is unlikely that intact cells were present, due to the lack of Y-chromosome-specific sequences in any of the female patients (Fivenson *et al.*, 2003a). Although speculative, these findings would seem to support the idea that some degree of gene transfer has occurred, bearing some similarities to gene therapy, in that the diseased tissue is exposed to a source of normal genes and their proteins (Fivenson *et al.*, 2003a; Fivenson and Falabella, 2000).

## IX. CONCLUSION

Tissue engineering is an emerging field, with engineered skin constructs playing a lead role. Like the natural tissue these constructs are designed to mimic, the engineered tissues are proving to be dynamic in the way they respond to environmental stimuli. The understanding of how these products induce healing is evolving. Greater understanding into how engineered tissues promote wound healing is being achieved through the research being done with Apligraf in different wound types. Initially the action was believed to be similar to skin grafts, where the patient's native tissue was replaced with the graft tissue. It is now believed that the mode of action is more complex. Cell therapy appears to be the primary mode of action; however, there may be other secondary mechanisms at work as well. The work being done in this area is very exciting, and researchers have only begun to scratch the surface in terms of understanding the mechanisms and environmental stimuli involved.

- II. Current Challenges
- III. Clinical Applications

- IV. Conclusion
- V. References

### I. INTRODUCTION

The overall impact of tissue engineering, as a multidisciplinary field, to clinical practice has been fairly diverse in nature. Directly or indirectly, it has enhanced our understanding of the structure–function relationships within normal and pathological tissues and of three-dimensional physiological processes. It has also broadened the possibilities for testing pharmacological therapies (Griffith and Naughton, 2002). Still, the benchmark for success remains, ultimately, its ability to generate new and more effective therapies for patients afflicted with severe tissue loss and/or organ failure (J. P. Vacanti, 1988). Only a handful of tissue-engineered products has reached the bedside, to date. Most of the clinically validated tissue-engineering therapies thus far have yielded modest benefits, often in small, well-defined patient populations. Besides, a long list of tissue-engineered products has either been abandoned during phase I/II trials or has failed in phase III testing (Lysaght and Hazlehurst, 2004). As with many other novel medical technologies, translation from the bench to the bedside has not been easy, and many hurdles remain to be surmounted. Perhaps this should not come as a surprise, in that the field is still maturing. The purpose of this chapter is to offer a general outlook on the present state of clinical application of tissue-engineering technology and its challenges for

further development. More detailed reviews of certain specific clinical applications are given in other chapters.

### II. CURRENT CHALLENGES

#### Practical Considerations

Timing is an inherent limitation of many tissue-engineering concepts. Except for tissue-inducing substances, autologous cell-based approaches generally involve weeks, if not months, of processing, for example, for the culture of a sufficient number of cells for a given composite construct. Yet time is often an unaffordable luxury for many patients. Another practical barrier has been the cost of this technology. Elaborate and expensive infrastructures are necessary for the development and manufacture of engineered tissue. So-called good manufacturing practice (GMP) facilities are a prerequisite for FDA approval of cell-based therapies, which, in turn, cannot be pursued without a critical mass of highly trained personnel. Furthermore, certain tissues require preconditioning in complex bioreactors, which may not be readily amendable to scaled-up manufacturing and shipping (Griffith and Naughton, 2002). All of these issues translate into a chronic difficulty in establishing multicenter clinical trials, which are essential for the widespread application of this technology.

## Regulatory Matters

Regulatory constraints have significantly hampered the clinical translation of many tissue-engineering therapies (Ahsan and Nerem, 2005). In the United States in particular, the FDA has been notoriously slow in initiating and conducting product-approval processes. This problem has been attributed, at least in part, to the lack of clear regulatory frameworks and to uncertainties regarding whether tissue-engineered products should be classified as mechanical implants, biological materials, or both.

Regardless, for many companies devoted mostly to tissue-engineering technologies, these regulatory delays, combined with strict reimbursement policies and poor business models, have often been commercially unsustainable. Indeed, many firms with considerable interest in tissue engineering have exited the market since the turn of century. Other American biotechnology companies have begun collecting clinical data overseas at lower costs, given that some European Union and Asian countries have less stringent regulatory procedures with regard to the marketing and clinical application of novel medical devices.

## Engineering Limitations

Perhaps surprisingly for some, the ideal cell type for many clinical applications of tissue engineering has not necessarily been determined yet. In many cases, while differentiated autologous cells would be ideal, their use simply may not be a viable option, either because of current isolation and expansion limitations (e.g., hepatocytes, neurons, cardiomyocytes, pancreatic islets cells) or because they tend to dedifferentiate over time (e.g., chondrocytes). Furthermore, even autologous cells in culture may not be completely free of pathogens, since the growth medium often requires xenogeneic growth factors, such as fetal bovine serum, or the cells can only propagate on murine feeder layers, so infectious risks cannot be completely eliminated. Of course, adult and embryonic stem cells, along with therapeutic cloning, could provide solutions to all of these problems. This is discussed in depth in other chapters.

The ideal biomaterial for a given clinical application often has also yet to be determined. Many of the currently available synthetic scaffolds are still limited by foreign-body reaction when placed in an immunocompetent environment. These conditions can lead to a reduction in the diffusion of nutrients and waste products, fibrosis, and other complications. Additionally, the cytotoxic effects of macrophage-generated nitric oxide can reach and destroy the transplanted cells. Thus, it is not surprising that most of the scaffolds that have been implanted in humans to date are derived from natural sources (e.g., bone, dermis, intestinal submucosa). However, natural scaffolds have been associated with unfavorable mechanical properties (e.g., rapid or inconsistent degradation, low tensile strength). For these

reasons, there remains a continued interest in the development of novel biocompatible synthetic biomaterials, such as elastomers. Scaffolds impregnated with growth factors or specific peptide sequences may also allow for better control of the surrounding microenvironment. Undoubtedly, these newer synthetic materials, further discussed in other chapters, will be instrumental in helping to broaden the type of tissues that can be engineered for human use.

## Blood Supply

Typically, any tissue greater than 1 cm in thickness cannot rely solely on vascular ingrowth from the host's vascular bed in order to remain viable *in vivo*. Thus, a major challenge for clinical application of large engineered tissues and engineered organs has been how to optimize the blood supply to the graft at the time of implantation. One interesting, now-already-preclinical approach to address this problem has been to create a preformed microcirculation within the engineered scaffold itself. Such a strategy has been employed by Vacanti and his colleagues using micro-electromechanical systems (MEMS) technology (Fidkowski *et al.*, 2005). Preliminary work has enabled his group to develop a robust computational model of the vascular circulation, which includes the fractal nature of network topology, the rheology of blood flow through this computational system, and the mass transfer of oxygen and nutrients across the vascular bed. More recently, this method has allowed this group to etch vascular channels onto silicon wafers, which can then be transferred to biodegradable polymer systems. Multiple monolayers of this architecture can be stacked to form three-dimensional structures. Two other approaches to address the problem of vascularization — gene therapy and the scaffold-based encapsulation of angiogenic growth factors (e.g., vascular endothelial growth factor) — have also been pursued in preclinical models. Conceivably, these approaches might be applied in facilitating the formation of other complex accessory networks (e.g., neural, lymphatic, biliary) as well, within engineered tissue.

## III. CLINICAL APPLICATIONS

A proper overview of the current state of clinical application of tissue engineering demands a proper understanding of the extent of the field (Fauza, 2003). Although some still link the term *tissue engineering* solely to the paradigm of cell delivery within biocompatible scaffolds, the theme is certainly much broader (J. P. Vacanti and Langer, 1999). In essence, all tissue-engineering technologies fall into one of four main strategies: (1) delivery of isolated cells (cell transfers), (2) tissue-inducing substances, (3) extracorporeal and encapsulation techniques (closed systems), and (4) transplantation of cell within matrices (open systems). A summary list of selected tissue-engineering products representing all these strategies, which either have reached mainstream clinical practice or were undergoing clinical

trials as of early 2006, is given in Table 78.1. Select general discussions follow, while more detailed information on certain specific applications can be found in other chapters.

### Cell Transfers

This approach involves simple injection or implantation of cells previously manipulated *ex vivo*, in the absence of matrices. The cells, whether autologous, allogeneic, or xenogeneic, may be altered by genetic, chemical, mechanical, or electrical stimuli prior to delivery. The aim of all cell transfers is to facilitate long-term cell engraftment, with the subsequent formation of new functional tissue, typically through the migration of host stroma and blood vessels. Perhaps the best and most successful example of this methodology is hematopoietic stem cell transplantation, which was first performed in humans in the 1950s, has long been well established clinically, and will not be further explored

here. Other, more recent cell transfer-based therapies are briefly examined next.

### Knee Cartilage Repair

Full-thickness injuries to articular joint cartilage often do not heal, at least in part due to their avascular nature. Various orthopedic procedures, including removal of damaged meniscal tissue, microfracture, and articular resurfacing, are performed to treat these often-debilitating problems. While these techniques can be effective in terms of restoring a smooth articular surface, the functional results can be suboptimal because none of these methods induces regeneration of resilient and durable articular cartilage.

In 1997, Carticel®, an expanded chondrocyte preparation produced by Genzyme Biosurgery, became the first commercially available tissue-engineered product for the management of cartilage defects. To date, over 10,000

patients have been treated with it worldwide. From a small cartilage biopsy obtained from a less weight-bearing area, approximately 12 million chondrocytes are grown *in vitro* over a five-week time period. The cells are then injected into the area of articular cartilage damage beneath a periosteal flap at a density of 1.6 million cells/cm<sup>2</sup>.

This autologous chondrocyte therapy is currently approved for use in selected patients with localized traumatic injury to the femoral condyle. The procedure can be particularly useful for the treatment of large single defects of up to 15 cm<sup>2</sup> or for the repair of multiple small defects. The original FDA approval of Carticel® was based on promising observational data in patients with full-thickness cartilage defects of the knee. In the seminal case series published by a Swedish group in 1994, 14 of the 16 patients with severe cartilage defects of the knee had good-to-excellent functional results (Brittberg *et al.*, 1994).

Nonetheless, in spite of the positive results using this product since 1997, the actual effectiveness and role of this therapy in the management of knee cartilage defects have remained somewhat unclear. In more recent, controlled studies, Carticel® has not been shown to be significantly better when compared with alternative approaches for joint-cartilage resurfacing (Bentley *et al.*, 2003; Horas *et al.*, 2003; Knutsen *et al.*, 2004). In one of these studies, autologous chondrocyte transplantation has demonstrated some good short-term results, as judged histologically and by the Short Form-36 score, but was shown not to be significantly different from microfracture after 24-month follow-up (Knutsen *et al.*, 2004). Clearly, long-term data will be required to determine the ultimate value of autologous chondrocyte transplantation among the various other treatments for traumatic knee injuries.

### Cellular Cardiomyoplasty

Every year, approximately 1.3 million individuals suffer a nonfatal myocardial infarction in the United States. Unfortunately, the myocardium cannot repair itself after these episodes, seemingly because of the absence of sufficient myocardial stem cells. The end result is therefore fibrotic scarring, resulting in a decrease in the ventricular ejection fraction and overall myocardial performance.

Recently, the local implantation of autologous skeletal muscle satellite cells or bone marrow-derived stem cells, a procedure now known as *cellular cardiomyoplasty*, has been evaluated as an experimental therapy in patients with ischemic myocardium. To date, over 200 patients have received this therapy worldwide. This approach aims to prevent the deleterious fibrotic remodeling of the injured myocardium by populating the damaged area with myogenic precursor cells. Support for this hypothesis has been based largely on animal data, which have shown that implanted cells can differentiate into multinucleated myocytelike cells, resulting in improved global ventricular

function without requiring electromechanical coupling between the implanted cells and host cardiomyocytes (Murry *et al.*, 2005).

At this time, the clinical feasibility of the cell transfer approach in the management of ischemic heart disease has only been described in multiple descriptive pilot studies (Murry *et al.*, 2005). It has been shown that hundreds of millions of myoblasts can be grown from a small muscle biopsy under GMP conditions using either autologous or fetal bovine serum. Several uncontrolled studies have demonstrated modest improvements in ejection fraction and regional wall activity after skeletal myoblast transplantation (Herrerros *et al.*, 2003; Menasche *et al.*, 2003; Siminiak *et al.*, 2004). At least two small randomized trials using autologous bone marrow mesenchymal cells have also demonstrated improvements in cardiac performance, including increased myocardial fluorodeoxyglucose uptake, enhanced wall motion, a reduction in ventricular end-systolic and end-diastolic volumes, and a net increase of 14% in ejection fraction when compared with a saline-infused control group (Chen *et al.*, 2004; Murry *et al.*, 2005).

The mechanisms for the observed benefits after clinical cellular cardiomyoplasty remain unknown. Because cell survival after the procedure appears to be quite low, proponents have speculated that the improved myocardial indices may be secondary to other factors, including increased angiogenesis, minimization of deleterious ventricular remodeling, and/or enhanced cytokine-mediated resident cell survival. Regardless of the mechanisms involved, additional studies are clearly needed in order to adequately assess the risks and benefits of cellular cardiomyoplasty. Whether or not direct myocardial injection of cells may also be associated with an increased risk for malignant arrhythmias warrants further scrutiny as well.

Several products based on the principle of cellular cardiomyoplasty are currently being tested in controlled trials, both in the United States and in Europe. One such therapy, marketed as MyoCell™ (Bioheart, Inc.), involves a collaboration of over 30 centers in Europe and has enrolled over 60 patients to date. In this approach, autologous skeletal myoblasts are expanded *ex vivo* and supplied as a cell suspension in a buffered salt solution. The product is then delivered directly into the epicardium during coronary artery bypass grafting surgery. In the United States, a donor-derived bone marrow preparation, marketed as Provacel™ (Osiris Therapeutics), is currently being evaluated, with preliminary unpublished data suggesting that the product is safe when injected intravenously within seven days of a myocardial infarction.

### Ocular Resurfacing

Damage to the corneal-limbal epithelium can occur after chemical/thermal burns, Stevens-Johnson syndrome, and ocular cicatricial pemphigoid. In severe cases, the

underlying bulbar conjunctival cells cannot sufficiently regenerate a normal ocular surface, leading to fibrovascular scarring and subsequent corneal opacification and blindness. Corneal transplantation from an allogeneic donor has long been an accepted therapy in selected cases. However, all transplanted patients require chronic immunosuppressive therapy in order to prevent graft rejection.

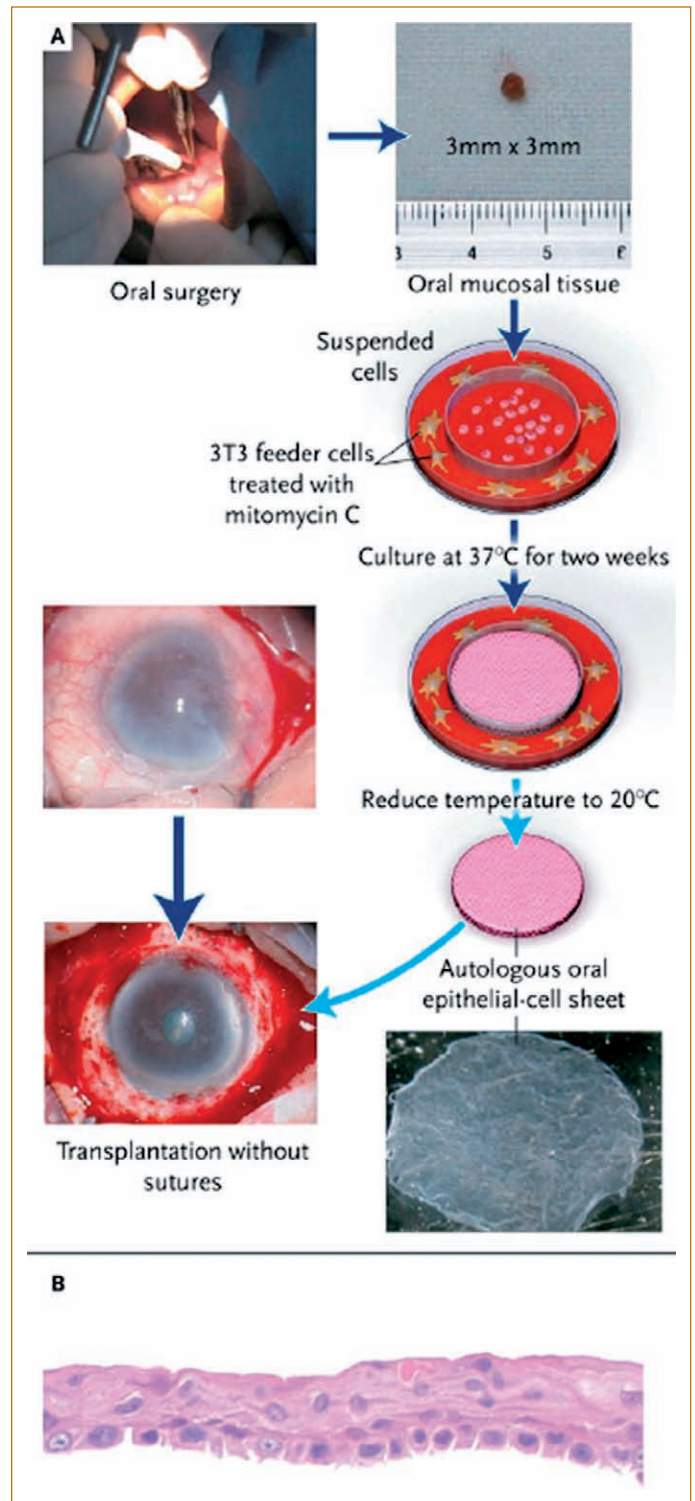

Recently, an alternative approach has emerged using transplanted epithelial sheets derived from expanded autologous cells. This technique was first reported in 1997 in two patients with complete loss of the corneal-limbal epithelium (Pellegrini *et al.*, 1997). They had near-total blindness in one eye after an alkali burn injury and underwent ocular resurfacing using autologous sheet grafts (approximately  $1 \times 10^5$  cells each) cultured from a 1-mm<sup>2</sup> biopsy obtained from contralateral healthy limbus. A contact lens was placed over the graft to facilitate engraftment. After more than two years of follow-up, both patients reportedly maintained dramatic improvements in visual acuity. Clinical case reports by other groups have since confirmed limbal cell transplantation as a viable approach to ocular resurfacing (Tsai and Chen, 2000). A phase I clinical trial using cells cultured under FDA guidelines has recently been initiated.

Taking this concept one step further, ocular resurfacing using autologous epithelial cells has also been described in the setting of bilateral disease. Recently, several groups have reported their clinical experience in a small series of patients using oral mucosal epithelium as a cell source for reconstruction (Nishida *et al.*, 2004; Inatomi *et al.*, 2006). The cells were obtained from autologous buccal mucosa and were cultured on mouse fibroblast feeder layers. Various carriers, including amniotic membrane and temperature-responsive culture dishes made from poly(*N*-isopropylacrylamide), were used to facilitate expansion and transfer of these cells onto the diseased corneal bed (Fig. 78.1). Thus far, mid-term results at two years postoperatively have shown improved visual outcomes in many, but not all, patients (Inatomi *et al.*, 2006).

### Dopaminergic Cell Transplantation

Parkinson's disease, a disorder caused by a selective loss of mesencephalic dopaminergic neurons within the substantia nigra, is a common and debilitating neurodegenerative disorder. Affected patients have characteristic symptoms, including slowness in voluntary movements (bradykinesia), resting tremors, muscle rigidity, and gait disturbance. Current medical therapy, including the exogenous administration of dopamine (levodopa), can be effective in many patients but in some cases is associated with numerous secondary motor complications.

One type of cell transfer, the transplantation of human fetal dopaminergic cells, has been studied in recent years as a potential treatment for Parkinson's disease. Initial observational studies suggested prolonged survival of the

**FIG. 78.1.** Transplantation of autologous engineered cell sheets fabricated from oral mucosal epithelium. **(A)** Oral mucosa is removed, grown to form into cell sheets in culture, and transplanted directly onto the diseased eye. **(B)** Photomicrograph showing multilayered cell sheets that do not resemble the original oral mucosa. From Nishida *et al.* (2004).

transplanted cells as well as substantial neurologic improvements in a number of patients, in the absence of medication. Nevertheless, at least two published, randomized controlled trials comparing the effectiveness of human fetal cell transplantation with sham surgery demonstrated no significant differences between the two groups, except for some modest gains in a cohort of younger patients (Freed *et al.*, 2001; Olanow *et al.*, 2003). Furthermore, both the impractical and ethical aspects of human fetal cell transplantation for Parkinson's disease have precluded its widespread clinical application. Porcine fetal nigral cell transplantation has been reported to provide some benefit for Parkinson's disease in one phase I study (Fink *et al.*, 2000). However, this procedure ultimately proved no better than placebo in a subsequent, unpublished controlled trial.

Currently, a number of investigators have shifted their focus from fetal cell transplantation to other cell transfer approaches that employ either embryonic or neural stem cells. Both cell sources have a high capacity for self-renewal, which could conceivably supply an abundant number of neurons for the treatment of Parkinson's disease. One biotechnology firm, NeuroGeneration, has recently initiated some early-phase clinical trials using autologous neural stem cells. In their approach, a needle biopsy of the brain is performed to harvest neural cells. Neural stem cells are then isolated from the sample, cultured, and differentiated into dopaminergic neurons over a six- to nine-month period prior to injection into the putamen. Based on as-yet-unpublished studies, this technique has been associated with an 83% increase in clinical scores after one-year follow-up.

### Myoblast Transfer Therapy

Duchenne muscular dystrophy (DMD) is an X-linked genetic disorder caused by a defect in the encoding for dystrophin, a muscle-fiber-stabilizing protein. The disease results in chronic mechanical injury to skeletal myocytes, leading to a vicious cycle of myocyte degradation and fibrosis. By early adolescence, most affected children are wheelchair-bound; by early adulthood, most individuals develop severe respiratory failure and cardiomyopathy. Unfortunately, in spite of significant advances in our understanding of the pathophysiology of DMD, its management continues to be largely supportive, and there has yet to be any effective therapy for this disease.

One experimental approach to the treatment of DMD has been the transplantation of muscle precursor cells from normal donors into dystrophic host muscle, a procedure known as *myoblast transfer therapy* (MTT). The goal of MTT is to enable relocalization and expression of normal functional dystrophin transcripts within the host muscle. This approach was originally shown to have promising results in animal models using *mdx* mice. Clinically, there was also evidence of dystrophin transcript expression in DMD patients by reverse-transcriptase polymerase chain reaction (Law *et al.*, 1992).

Unfortunately, multiple clinical trials to date have not shown any objective benefit in DMD patients injected with donor myoblasts. In one of the initial human studies, dystrophin-positive fibers made up to 36% of the injected muscles after one month (Gussoni *et al.*, 1992). However, the levels of expression have generally been undetectable by six months postinjection. In a subsequent American study employing serial injections over a six-month time period, normal myoblasts harvested from the skeletal muscle of unaffected relatives also did not show any clinical benefit when transplanted into the skeletal muscles of affected boys (Mendell *et al.*, 1995).

The disappointing clinical results to date have likely to do with multiple factors, including poor cell survival, immune rejection, and limited cell distribution after injection. To our knowledge, no clinical trials of MTT are currently ongoing. Nonetheless, the past several years have witnessed a renaissance in preclinical efforts to enable MTT. These studies are attempting to address some of the shortcomings of the previous human studies, using better immunosuppressive regimens and alternative stem/progenitor cell sources (e.g., muscle-derived stem cells), among other approaches (Urish *et al.*, 2005).

### Other Cell-Transfer Applications

Other clinical applications of cell transfers have also been reported. Examples include either eminently anecdotal experiences, such as the intraportal injection of gene-transfected hepatocytes previously isolated from the recipient's own liver, as a means to reduce cholesterol levels in homozygous familial hypercholesterolemia, or better-established methods, employed in larger patient populations, such as pancreatic islet transplantation for type I diabetes. Recently, a Canadian group has reported an approximately 85% insulin-free rate at long-term follow-up after pancreatic islet cell transplantation (Shapiro *et al.*, 2000). Unfortunately, these clinical results have been difficult to replicate elsewhere, and more widespread application of this procedure continues to be hampered by difficulties in harvesting large numbers of islets and by the inability to expand these isolated cells *ex vivo* without senescence or dedifferentiation. Moreover, the procedure requires immunosuppressive therapy. In recent years, enthusiasm for a xenogeneic approach using porcine islet cells has dwindled somewhat because of increasing concerns regarding the introduction of porcine endogenous retroviruses (PERV) into humans. Further discussion of these other applications of cell transfer-based therapies are not within the scope of this chapter.

### Tissue-Inducing Substances

Tissue-inducing substances are injectable or implantable materials, devoid of any cells, that can stimulate, modulate, or guide the formation of new tissue *in situ*. This can be achieved via different mechanisms. These substances

may provide the appropriate substrata for host cells to reorganize and develop into three-dimensional tissue. They may maximize gas exchange as well as nutrient and waste diffusion. Additionally, they may boast bioactive signals, such as cell-adhesion peptides and growth factors, which can be loaded or embedded within these materials to enhance tissue remodeling.

One of the major advantages of this approach has been its practicality as a biological substitute. Unlike cell-based therapies, they can be applied without extensive training. Moreover, they have enjoyed greater appeal among clinicians due to their true off-the-shelf availability. To date, a number of commercially available tissue-inducing substances have been employed across many surgical disciplines, most of them directed at skin or bone repair.

### Dermal Substitutes

Full-thickness burn injuries destroy both the epidermis and the dermis, leaving the skin unable to regenerate on its own. The use of meshed, split-thickness autologous skin grafts (autografting) has been the traditional method for covering full-thickness burn injuries. Unfortunately, this technique is also accompanied by high donor site morbidity and can produce undesirable cosmetic and functional results secondary to hypertrophic scarring. When full-thickness burn injuries are extensive (e.g., greater than 50% of total body surface area), achieving adequate burn wound coverage can be considerably more challenging because of the lack of autologous donor sites. Although alternative materials for burn wound coverage, including allograft, xenograft, and synthetic dressings, can be used, these products generally lead to suboptimal outcomes.

The Integra® dermal regeneration template (Integra Life Sciences) is one of many off-the-shelf acellular products currently available for skin regeneration. It was originally described by Yanniss and Burke over 20 years ago (Burke *et al.*, 1981) and remains the most widely accepted engineered product for patients with large burns. Integra has a bilaminar structure, consisting of cross-linked bovine collagen and chondroitin sulfate on the lower surface and an upper silicone membrane that serves an epidermal function. The pore size of the lower layer has been designed specifically to provide a template for the regeneration of dermis, as opposed to scar, by facilitating the controlled migration of host endothelium and fibroblasts. Once the neodermis is established (usually after three to six weeks), the silicone layer is removed, and an ultrathin (e.g., 0.15 mm) split-thickness skin graft can be applied.

Integra has been one of the best-studied tissue-engineered products to date. In a large multicenter, randomized trial, burn wounds treated with Integra healed faster and had less subjective hypertrophic scarring when compared to other materials (Heimbach *et al.*, 1988). Engraftment rates consistently range between 80% and 90%, and donor site morbidity is decreased, in part because of

faster healing at the donor sites. The long-term results also tend to be quite favorable (Heimbach *et al.*, 2003). Almost 10,000 patients have received this product for the management of burns worldwide, up to now.

### Demineralized Bone

The gold standard for reconstruction of major bone defects resulting from trauma, tumors, or infection is autologous cancellous bone. However, donor site complications, such as infection, hematoma, severe pain, and iliac wing fracture, are known to occur with some frequency. In addition, not infrequently there is a limited supply of autologous tissue, particularly in geriatric and pediatric patients. Cadaveric allografts can be used to circumvent some of the problems associated with autografts, but allograft supplies continue to be outstripped by the ever-growing demand for them. Moreover, concerns remain about possible disease transmission with allograft use. These limitations of conventional bone reconstruction techniques have spurred an ongoing interest in alternative tissue-inducing matrices, commonly referred to as *osteobiologics*. These materials are essentially graft substitutes with osteoconductive and osteoinductive properties that enable them to induce new bone formation.

Over the past decade, demineralized bone matrix (DBM) has been one of the most commonly employed osteobiologic materials. DBM is produced by a special demineralization processing of human cadaveric bone using hydrochloric acid. The resultant matrix is composed of 90% type I collagen and 10% noncollagenous proteins. DBM is also rich in bone morphogenic proteins (BMPs) and other osteogenic factors. Currently over half a dozen commercially available DBM products are on the market in the United States. A variety of formulations, including a powder and an injectable substrate, have been used clinically. DBM is currently used in combination with autologous bone or bone marrow, and it is approved for use in a number of settings in periodontal and orthopedic surgery. Although there appears to be some variability in the osteoinductive capacities of DBM, depending on its processing method and donor source, this material has been shown to facilitate bone healing when implanted into a fracture, arthrodesis, and other contained bone defects.

Still, in spite of its fairly widespread clinical acceptance, there has been a striking paucity of well-designed clinical studies documenting its effectiveness when compared to other reconstructive approaches. In one of the few prospective trials to date, a combination of DBM and an autograft led to similar healing rates after spinal fusions when compared to autografts alone (Cammisa *et al.*, 2004). Controlled data in other reconstructive settings are lacking. Further developments in osteoinduction driven by native insoluble bone morphogenetic protein and noncollagenous protein aggregates remain a continuing interest in the field.

## Closed Systems

In closed systems, construct cells are sequestered from the host, usually via a semipermeable membrane that allows for the bidirectional transport of nutrients and wastes. By manipulating the membrane pores, closed systems can be specially designed to prevent the diffusion of certain macromolecules, such as antibodies and complement, as well as lymphocytes, thereby preventing them from destroying the cells within the construct at the same time that beneficial/therapeutic donor cell products can be released into the host.

Closed systems can be subdivided into intracorporeal and extracorporeal. In intracorporeal systems, the transplanted cells are isolated from the host by either microencapsulation or macroencapsulation technologies. Microcapsules generally offer better flow of nutrients and wastes than macrocapsules and can be administered by injection. Macrocapsules, on the other hand, are physically more stable and easier to retrieve, should complications occur. In extracorporeal systems, the patient's blood or plasma is pumped *ex vivo* into a device housing living cells, which are separated from the blood/plasma by a semipermeable membrane prior to infusion back into the patient.

## Encapsulated Pancreatic Islet Cells

For decades there has been considerable interest in alternative cell-based therapies to pancreatic islet transplantation for type I diabetes. More recently, interest in islet cell encapsulation, a concept first introduced in the 1970s, has been renewed at multiple centers. Unfortunately, consistent clinical success with this approach has proven to be a formidable task, partly because of biocompatibility issues with the encapsulation membrane (Scharp *et al.*, 1994; Soon-Shiong *et al.*, 1994). Nevertheless, some progress has been made. For example, a recent uncontrolled trial using encapsulated porcine islets has suggested a decrease in insulin requirements in a subset of patients with diabetes (Valdes-Gonzalez *et al.*, 2005). In addition, at least one prospective phase I/II clinical trial is currently under way in Canada evaluating the effectiveness and safety of intraperitoneal injections of alginate-encapsulated human islet cells and low-dose, short-term immunosuppression in diabetic patients. Should these methods eventually be validated, they could have a major impact on the treatment for this disease.

## Bioartificial Liver

Acute liver failure can stem from a number of conditions and has been associated with mortality rates ranging from 60–90%. Its treatment remains largely supportive, with the only definitive therapy still being liver transplantation. Due to the chronic shortage of donor livers, a considerable number of patients die while waiting for an available organ.

A device that could reliably serve as either a bridge to liver transplantation, or as a temporary therapy until the native liver function is recovered, would represent an important breakthrough in this setting.

Recent clinical experience has been reported with a number of extracorporeal liver-support devices. For example, the ELAD® (Extracorporeal Liver Assist Device, Vitagen) uses a dual-pump dialysis system and hollow-fiber cartridges containing C3A cells derived from a human hepatoblastoma cell line. Plasma is ultrafiltrated through the fibers into the extracapillary space of the cartridge, where it comes in direct contact with the hepatocytes. Although the ELAD has been shown to be reasonably safe and to lead to improvements in clinical as well as biochemical parameters, no survival benefit was observed in an initial controlled study (Millis *et al.*, 2002). Subsequent refinements in the design of the apparatus have prompted its re-evaluation in currently ongoing clinical trials.

Another liver-support system, the HepatAssist® (Circe Biomedical), has also been tested in clinical trials. In contrast to the ELAD, the HepatAssist uses porcine hepatocytes attached to collagen-coated microcarriers (Fig. 78.2). Similar to the experience with the ELAD, however, unfortunately the original data from a large, randomized controlled trial

**FIG. 78.2.** Schematic outline of the HepatAssist® device loaded with microcarrier-attached porcine hepatocytes. From Demetriou *et al.* (2004).

did not show an increased survival in the majority of patients exposed to this device. Although a small survival benefit was subsequently reported in a subgroup of patients with fulminant/subfulminant hepatic failure (Demetriou *et al.*, 2004), given the overall modest results, this device has yet to be approved for clinical use by the FDA. A newer-generation device, termed the HepatAssist-2® (Abios Systems), contains a number of design upgrades, including a threefold increase in hepatocyte mass. It is currently being tested in phase III clinical trials.

### Bioartificial Kidney

Renal failure is currently managed by hemodialysis, peritoneal dialysis, hemofiltration, or kidney transplantation. The roles of these therapies in providing adequate fluid clearance and in removing small and middle-sized solutes from the blood in patients with chronic renal failure are well established. Unfortunately, these treatment modalities have been shown to be less effective in critically ill patients with acute renal failure (ARF), with mortality rates in excess of 70%.

The bioengineered kidney has been proposed as a more effective therapy for the management of ARF. Since the death of most ARF patients is associated with a systemic inflammatory response syndrome, it has been postulated that a more complete device, offering filtration, metabolic, endocrine, and immunoregulatory functions similar to those performed by the native kidney, might lead to improved outcomes. To test this hypothesis, a bioengineered renal replacement system has been developed and tested in early phase trials by Humes and his colleagues at the University of Michigan. This renal tubule-assist device (RAD) consists of a conventional high-flux hemofilter followed in series by human renal tubular cells that have been grown to confluence along the inner surface of hollow fibers. In a small, uncontrolled clinical study in critically ill patients, these devices were used for up to 24 hours and demonstrated increased survival as well as differentiated metabolic and endocrine activity, as shown by glutathione degradation and the conversion of 25-OH-D<sub>3</sub> to 1,25-(OH)<sub>2</sub>-D<sub>3</sub>, respectively (Humes *et al.*, 2004). Based on these data, a randomized, phase II trial, initiated in conjunction with RenaMed Biologics, is currently ongoing for patients with ARF secondary to acute tubular necrosis.

### Open Systems

In open systems, cells are seeded onto scaffolds that help guide their organization into the appropriate architecture (J. P. Vacanti and Langer, 1999). Also here, clinical experience has been largely anecdotal. For instance, engineered bone based on a natural coral scaffold has been successfully implanted in a patient who sustained a traumatic left thumb avulsion (C. A. Vacanti *et al.*, 2001). In another report, the native pulmonary valve was replaced with a decellularized pulmonary artery allograft that had been seeded with autol-

ogous vascular endothelial cells (Dohmen *et al.*, 2002). Other investigators have recently described case reports ranging from the engineering of bone for craniofacial reconstruction to the creation of engineered respiratory airway tissue for a bronchopleural fistula (Macchiarini *et al.*, 2004; Warnke *et al.*, 2004). A case series from Italy has reported on the efficacy of a hyaluronan-based scaffold seeded with autologous chondrocytes for the repair of knee cartilage defects (Marcacci *et al.*, 2005). Many isolated cases also remain unpublished (e.g., of chest wall repair using autologous chondrocytes). Albeit not yet disclosed, early reports on other applications are expected, such as engineered blood vessels for renal dialysis access, bone marrow-based constructs for bony nonunions, and different engineered constructs for the treatment of various urological diseases.

A few applications of open-system tissue engineering, however, have involved more sizable patient populations, even though the relevance of that experience has often been curbed by trial design limitations.

### Composite Skin Grafts

Foot ulcers are common complications of diabetes. Although most of these wounds eventually resolve under conventional wound management, many do not heal within three weeks. In some of these cases, serious infections can arise, and amputation may be the only option for definitive management. In an attempt to improve this scenario, a number of engineered skin constructs have been introduced clinically in recent years, as an adjunct to conventional wound management.

At this time, Apligraf™ (Organogenesis), which consists of human allogeneic neonatal keratinocytes and fibroblasts within a bovine dermal matrix, is one of the most widely used of these constructs. Its application in diabetic ulcer wounds has been validated in a randomized clinical trial (Veves *et al.*, 2001). In that study, Apligraf™ plus optimal wound care demonstrated statistically faster rates of wound healing when compared to optimal wound care alone. Despite the allogeneic nature of the product, no signs of clinical rejection were observed. Apligraf™ is also approved for the management of long-standing venous stasis ulcers (Falanga *et al.*, 1998). Experiments on the effectiveness of Apligraf™ in other settings, such as in the management of acute surgical wounds, burn wounds, and select severe congenital skin disorders, are currently under way.

At the same time, several important questions remain. For example, it is not yet known whether patients with a high risk for a poor outcome (e.g., due to the size and duration of the ulcer) might benefit from an earlier application of these products. In addition, the long-term benefit of a composite allogeneic skin construct has been questioned by some investigators, for at least one study has shown a lack of significant lasting engraftment of the Apligraf™-derived cells (Griffiths *et al.*, 2004). These findings suggest that this product may essentially act more as a temporary (i.e.,

**FIG. 78.3.** Macroscopic and scanning electron microscopic appearance of biodegradable scaffolds used for cardiovascular tissue-engineered conduits. The scaffolds are based on a copolymer of lactide acid and polycaprolactone. From Shin'oka *et al.* (2005).

four-weeks' duration) biological dressing, rather than as a bona fide permanent skin substitute.

#### Pediatric Cardiovascular Conduits

An engineered vascular conduit would be highly desirable for infants and children born with different forms of severe cardiovascular anomalies. Currently available homografts and synthetic prostheses are hampered by numerous problems, including thrombosis, limited durability, susceptibility to infection, and calcification. In addition, because most of these conduits essentially cannot grow, the need for one or more reoperative procedures later in life is the rule.

In recent years, a Japanese group led by Shin'oka has amassed substantial clinical experience with tissue-engineered conduits as vascular replacements in low-pressure systems. In 2001, they described their initial case report, a 4-year-old girl who developed total occlusion of the right intermediate pulmonary artery after a pulmonary artery angioplasty and a Fontan procedure and subsequently underwent reconstruction with an autologous vessel graft engineered from cells obtained from a peripheral vein (Shin'oka *et al.*, 2001). The construct remained patent for over seven months after implantation. That group has since reported their experience using a similar approach in over

40 children with varying forms of complex congenital anomalies (Fig. 78.3) (Matsumura *et al.*, 2003). Current methods are focusing on the use of uncultured, autologous bone marrow as the cell source for seeding scaffold tubes based on a copolymer of polylactic–polycaprolactone reinforced with woven polyglycolic acid (Hibino *et al.*, 2005; Shin'oka *et al.*, 2005).

Thus far, the midterm outcomes of engineered vascular grafts in children have shown no significant complications, as well as continued patency when followed up to a median time of 16.7 months postoperatively (Inatomi *et al.*, 2006). However, balloon angioplasty has been required in some cases because of tissue overgrowth at anastomotic sites. The long-term growth, remodeling, and durability patterns of these grafts remain unknown. Most importantly, there have been no well-controlled human trials comparing tissue-engineered conduits to those made only from synthetic materials. Without these data, the ultimate role of tissue engineering in this setting will justifiably continue to be questioned.

#### IV. CONCLUSION

Tissue engineering may be at the inflection point of a steep upward slope on its developmental curve. As evi-

denced in many examples discussed in this chapter and others, concrete clinical benefits from this technology have accumulated in the past several years, albeit still at a much slower pace than what we can realistically expect for the future. Although the widespread availability of off-the-shelf tissues and organs has yet to become a reality, the field is both exceedingly young and vibrant. Much remains

to be learned and developed, not only by scientists, clinicians, and entrepreneurs, but also by regulatory governmental agencies. Nevertheless, given its scientific premises, the potential magnitude of its impact to society, and what has been achieved thus far, many believe that it should only be a matter of time until tissue engineering reaches the mainstream of medical practice.

### I. INTRODUCTION

The culture of skin cells in organotypic systems has a comparatively long history, and such constructs have been seen as the simplest tissue-engineered products to fabricate. Accordingly, they are among the few tissue-engineered products that have reached the commercial market. This has brought the realization of many other factors, apart from materials and culture considerations, that are involved in the production of a successful commercial product. These include choice of scaffold cell sources, particularly the use of allogeneic cells, design of bioreactor, automation of the manufacturing process, cryopreservation, and distribution. Manufacturing takes place in a highly regulated environment, which imposes many constraints on design and strategic planning. These concepts are illustrated with the process involved in the manufacture of Dermagraft and TransCyte, taken as specific examples, including brief discussion of clinical trial experience and commercialization. Commercialization at this point involves, among other factors, satisfactory clinical trial results, demonstrating efficacy, an adequate rationale for the mechanism of action of the product, and an established reimbursement system from third-party payers. The principles covered in this discussion are summarized. To this point, therapeutic tissue-

engineered products have involved fibroblasts alone or fibroblasts and keratinocytes. In the future we may expect to see products involving adnexal structures, such as hair follicles, which represent one of the few examples of organogenesis from adult cells, and the development of alternative methods of stasis preservation, such as desiccation.

Skin-tissue engineering was perceived as the simplest tissue-engineering application and was the earliest to be explored. The culture of fibroblasts, derived from skin biopsies, was established early, and the cells were comparatively easy to grow and were used to develop many of the early systems of tissue culture. The culture of keratinocytes was achieved by Rheinwald and Green in the late 1970s (Rheinwald and Green, 1975) and, using a different system, by Karasek (S. C. Liu *et al.*, 1978). Skin biology was second only to immunology in the application of the techniques of molecular and cell biology to medical problems, which has led to great advances in the understanding of the physiology of skin. Examples of methods that have been applied include the use of classical techniques of molecular and cell biology and transgenic animals.

The skin acts as a barrier between internal structures and the external environment. In the 1980s it was realized that the skin, in addition to acting as a barrier, has

significant interaction with both the innate and the adaptive immune systems (Stingl *et al.*, 1978; Streilein, 1983; Stingl, 1989). It is, thus, much more than a passive barrier and actively recruits defensive mechanisms to protect against infection, colonization by microorganisms, and other external noxious entities.

With its long history of development, tissue-engineered skin substitutes have achieved market exposure and have some of the most extensive experience with the application of such products in a therapeutic setting. From its inception in 1979 (Bell *et al.*, 1979), engineered skin was seen as potentially a clinical product, and trials started in the 1980s. Preclinical testing was inaugurated and demonstrated that fibroblasts were apparently not rejected and persisted for a considerable period in experimental animals (Hull *et al.*, 1981, 1983; Sher *et al.*, 1983). This led to human clinical trials in the late 1980s and early 1990s. Tissue-engineered skin products first gained regulatory approval and appeared on the market in 1997. The first was TransCyte (Advanced Tissue Sciences), which was a nonviable burn product produced by tissue-engineering techniques. It was followed by Apligraf (Organogenesis) in 1998, the first tissue-engineered, viable, organotypic product, and Dermagraft in 2000. At the same time, many applications of such products for *in vitro* testing applications and models of skin physiology were developed.

Much of the discussion in this chapter is based on experience with Dermagraft and TransCyte. Both products have a similar basis in the growth of fibroblasts on three-dimensional scaffolds. The systems, however, differ substantially in detail. Dermagraft is grown on 2-inch  $\times$  3-inch sheets of a knitted polylactide/glycolide scaffold under static conditions in a bag bioreactor. Following seeding, the cultures are refed with medium every few days until harvest after about two weeks. Initially, the fibroblasts proliferate rapidly, much as in monolayer, but as they become confluent, at about eight to ten days, they lay down increasing amounts of extracellular matrix. At harvest, medium is replaced with cryoprotectant and the bioreactor is welded closed without exposure of the product to the environment, boxed, and frozen under controlled conditions. Dermagraft is stored below  $-65^{\circ}\text{C}$  for up to six months. During the first month, sterility and analytical testing is performed and the paperwork completed to allow release of the product by the Quality Assurance Department. On thawing, which is performed by the end user, the cells of Dermagraft show 50–80% viability.

TransCyte is grown, using a similar process, on two 5-inch by 7-inch sheets of a knitted nylon (nondegradable) scaffold with a silastic backing in a continuous-flow, hard bioreactor. This system has advantages in the ease of taking medium samples and in slightly superior cell growth, but it adds considerably to the complexity of the system. At harvest, the cultures are rinsed and the bioreactors are sealed from the system by welding, packaged, and frozen without any care taken to maintain viability.

The three-dimensional structures formed by the cells under these conditions consist of cells embedded in extracellular matrix that they, themselves, have secreted. It comprises a complex series of molecules. The process of secretion may be thought of as formation of a foreign body capsule *in vitro*.

## II. TYPES OF THERAPEUTIC TISSUE-ENGINEERED SKIN PRODUCTS

The development of tissue-engineered skin has taken two fundamentally different approaches using alternative methods for the three-dimensional culture of fibroblasts and a third that has intermediate characteristics. One is the use of fibroblasts suspended in collagen gel, in which the gel acts as a substrate for the growth of keratinocytes and forms a structure that has some resemblance to human skin. The second involves culture on a three-dimensional nonbiologically derived, polymeric scaffold. Fibroblasts are responsive to signals from their environment and respond in quite different ways to the two types of culture. In a third system, fibroblasts are grown on a collagen sponge in serum-containing medium. Since collagen adsorbs fibronectin and vitronectin, this system initially shows cell adhesion to collagen, fibronectin, and vitronectin, and the cultures show intermediate properties.

In collagen gel suspension, fibroblasts are surrounded by collagen, and respond through  $\alpha_1\beta_1$  and  $\alpha_2\beta_1$  integrins, which are collagen receptors, by becoming quiescent and nonproliferative (Langholz *et al.*, 1995). Characteristically, the collagen gel is contracted by the fibroblasts to less than 10% of its original volume in about 20 h, through the  $\alpha_2\beta_1$  integrin. At the same time, many genes, notably those for collagen type I and proliferation, are repressed (Eckes *et al.*, 1993), and the cells show mechanosensitivity (Kessler *et al.*, 2001). The collagen repression is mediated through the  $\alpha_1\beta_1$  integrin (Langholz *et al.*, 1995). If the gels are mechanically stressed, usually by preventing contraction with a ring, many genes, including collagen type I and proliferation-related genes, are somewhat induced relative to contracting gel fibroblasts, although not the level of monolayer fibroblasts (Kessler *et al.*, 2001). The cells also show a substantial up-regulation of genes associated with inflammation, such as the genes for IL-1, IL-6, and cyclooxygenase (Kessler-Becker *et al.*, 2004).

When grown on scaffolds, fibroblasts proliferate rapidly and then deposit large amounts of extracellular matrix. Initially, the conditions on the scaffold are not dissimilar from monolayer culture. The scaffold adsorbs proteins from the serum, which is a component of the medium still used for fibroblast culture. These include fibronectin and vitronectin, as in monolayer culture (Steele *et al.*, 1995). However, as the cells reach higher densities and the fibroblasts cease to proliferate, they proceed to lay down extracellular matrix at rates approaching their own weight per day. The matrix is

loose connective tissue, much like the provisional matrix of granulation tissue, and may be thought of as foreign-body capsule formation occurring *in vitro*. The cells are clearly very active and induce several genes, among the most notable of which are neutrophil chemoattractant chemokines CXCL1, CXCL5, CXCL6, and CXCL8. They also induce the expression of IL-6. The conclusion from these observations is that the fibroblasts act to recruit neutrophil granulocyte components of the innate immune system, which is important in responding to the most likely type of environmental insult to which the dermis is liable, physical injury followed by bacterial colonization.

### III. COMPONENTS OF TISSUE-ENGINEERED SKIN GRAFTS AS RELATED TO FUNCTION

#### Scaffold

Several types of scaffold have been employed for tissue-engineered skin implants. They include collagen gels, knitted polylactate/glycolate fabrics (PLGA), and collagen sponges. As discussed earlier, the scaffold has profound effects on gene expression and the function of the fibroblasts.

The Dermagraft and TransCyte processes used scaffolds obtained as finished commercial products from other companies, which already had regulatory approval. While this simplified the development of the products, it ultimately proved to be an expensive decision. A solution to this is to obtain a second source of raw material that is not a finished product and to establish its equivalence.

A further point here is that, while the use of already-approved products as scaffolds may be an easy initial path, the available materials may not be ideal for the particular application envisaged. There is a need to expand the range of scaffolds available for commercial tissue engineering. An example is enzymatically, rather than spontaneously, degrading scaffolds.

#### Keratinocytes

Keratinocytes generate the impervious surface of the skin (the stratum corneum) and also have been thought of as having a major role in defense against microbial colonization as activators of immune responses. As a consequence, keratinocytes have been included, either alone or in combination, with other components in many skin implants (Ansel *et al.*, 1990). Their role in forming a physical barrier is important, but they also have the ability to produce antimicrobial peptides, such as  $\beta$ -defensin, psoriasin, and cathelicidin (Nizet *et al.*, 2001; Harder and Schroder, 2005) and a wide variety of cytokines capable of activating immune responses (Pivarcsi *et al.*, 2004; Albanesi *et al.*, 2005). The epidermis contains antigen-presenting cells that are capable of activating T-lymphocytes, under suitable conditions, to both cell-mediated and humoral adaptive responses. This is

largely a function of Langerhans cells, but it is possible that the keratinocytes also take part under special conditions. It has been argued that the application of a bag containing keratinocytes to a wound, which would be permeable to proteins but not to cells, may be beneficial without incorporation of the cells into the patient (U.S. Patent 5972332).

It is notable that the keratinocytes show a higher expression of the fibroblast-stimulating growth factor PDGF- $\alpha$  chain gene than do fibroblasts. This may constitute part of the secretion of reciprocal paracrine growth factors by the epidermis and the dermis (Sato *et al.*, 1997). Such a pathway has been described by Fusenig, involving IL-1 $\alpha$  secretion by keratinocytes, which stimulates secretion of FGF-7 (keratinocyte growth factor 1), and GM-CSF, which promotes keratinocyte proliferation (Smola *et al.*, 1993). Such interactions may well be of importance during wound repair, when proliferation of both types of cells is important (Smola *et al.*, 1998).

In practice, allogeneic keratinocytes in skin implants appear to remain for some weeks and then disappear. This has been attributed to immunological rejection. But this is not clear because keratinocytes, cultured to the numbers required for implant, consist almost entirely of transiently amplifying cells that follow a differentiation pathway that leads to a modified form of apoptosis. They may, thus, be expected to be lost from the implant without the intervention of the immune system.

An approach that has been explored for increasing the coverage and survival of grafted epidermis is to mix allogeneic with autologous keratinocytes. This permits a comparatively small number of autologous keratinocytes, without extensive expansion, to cover a large area, by adding allogeneic keratinocytes (Rouabhia *et al.*, 1994). The allogeneic cells provide initial coverage, while the autologous population, which retains stemlike cells, provides the persistence. Most of the allogeneic cells are eventually lost, but the epidermis remains.

#### Fibroblasts

Fibroblasts are the major producers of extracellular matrix (discussed next). They are not antigen-presenting cells and have been regarded as not having a major role in interactions with the immune system. However, their ability to secrete neutrophil attractant chemokines CXCL-1, CXCL-4, CXCL-5, and CXCL-8 and the cytokines IL-6 and IL-11 (discussed later) suggests that they may have a more important role in activating innate immune responses.

Fibroblasts do not appear to produce significant quantities of defensins, cathelicidin, or other antimicrobial peptides. Their major antimicrobial activity appears to be through recruiting neutrophils.

#### Extracellular Matrix

Fibroblasts express a large array of extracellular matrix genes. Expressed genes represent collagens (types 1, 3, 5, 6),

proteoglycans (decorin, lumican), thrombospondins, fibulins, fibronectin, tenascin C, metalloprotease inhibitors, lysyl oxidase, tissue factor inhibitor, and SPARC. It also involves bound growth factors, such as FGF-2 and TGF- $\beta$ . The matrix involves multiple kinds of integrin ligand, including  $\alpha_1\beta_1$ ,  $\alpha_2\beta_1$ ,  $\alpha_3\beta_1$ ,  $\alpha_4\beta_1$ ,  $\alpha_5\beta_1$ ,  $\alpha_6\beta_1$ ,  $\alpha_v\beta_1$ ,  $\alpha_7\beta_1$ , and  $\alpha_6\beta_4$  and proteins known to modify adhesion. It provides complex stimulation that, since it is secreted by fibroblasts, is presumably appropriate for cell migration.

In systems where fibroblasts are cast in collagen gels, the initial signal is through the  $\alpha_1\beta_1$  and  $\alpha_2\beta_1$  integrin, and that remains the dominant stimulus until the cells elaborate other signaling molecules.

### Subcutaneous Fat

Subcutaneous fat has received little attention thus far in the engineering of skin. However, it has been shown to undergo major structural changes during the hair cycle in the mouse and is a highly vascular organ.

### Components of the Immune System

Inclusion of Langerhans cells has been accomplished in test systems but has not been applied to therapeutic products.

### Melanocytes

Other cells of the epidermis have been incorporated into test systems and have also been considered for transplant into epidermal tissue-engineered therapeutic products. An example is the inclusion of melanocytes as a treatment for vitiligo, which is a clinical problem in countries such as India. Systems including melanocytes have been used extensively in test systems for UV-protective preparations.

### Adnexal Structures

The self-assembly of hair follicles and their use as a therapeutic product is discussed later in this chapter. Inclusion of sweat glands has been explored, but they have not yet been included in tissue-engineered constructs. The early fear that patients treated with keratinocyte allografts might have problems with temperature control has not eventuated.

## IV. COMMERCIAL PRODUCTION OF TISSUE-ENGINEERED SKIN PRODUCTS

Commercial production takes place in a highly regulated system, which has many constraints if it is to be successful. These are discussed under a series of headings, dealing with physical constraints, such as bioreactor design, growth system design, and cell sources, and with broader considerations of the nature of preclinical and clinical assessment, regulation, reimbursement, and the marketplace. It is central to a commercial enterprise that it

ultimately make a profit if it is to be successful. Since tissue engineering is inherently an expensive undertaking, minimizing costs at all stages is essential.

### Regulation

Regulation of tissue-engineered products by the FDA or other regulatory authorities is developing. Since commercial products have only been available since 1997, and since they are very different from other medical products, establishing a regulatory pathway has been complex. Tissue-engineered skin substitutes do not fit readily into any of the standard FDA categories: drugs (CDER), biologics (CBER), and devices (CDRH). Classification is important because requirements, criteria, and guidelines differ substantially between the centers. Skin implants were originally considered dermal or skin replacements and classified as devices. As it became evident that growth factor activity played a part in their mode of action, considerations appropriate to biologics played an increasing role. There is now within the FDA an Office of Combination Products responsible for assembling reviewers from different FDA centers to form a team to review such products. While tissue-engineered skin substitutes generally have more biochemical activity than would be expected of a pure device, they do not fit easily as a biologic. For instance, the concept of “dose” is not straightforward. If a component of the activity of these materials is through secretion of growth factors, growth factor production would seem to be a reasonable release criterion. However, unlike a purified growth factor preparation, these products are living, and the secretion of growth factors may vary depending on conditions. The cells adjust their cytokine output to the environment in the wound bed. It may be possible to devise conditions under which growth factor (for instance, VEGF) secretion is maximal (with optimal PDGF stimulation) and to determine output under those conditions. To avoid such problems, a “dose” of Dermagraft has been defined as a piece.

Also, at this stage the composition of tissue-engineered skin can only be determined to a limited extent. Usually, it is desirable that a biologic contain well-defined constituents, as in an active ingredient, at a known dose, and excipients. Thus far, studied components of skin implants have included those that are known and, to some degree understood, from other work. There is no comprehensive identification of constituents, and several that appear on expression arrays, such as lumican and collagen type 6, which appear prominently on arrays, have received inadequate attention.

### Product Development

Development of a commercial product should start with a *product concept*, from which a *design requirements* document is developed. As an example, Table 79.1 shows the product concepts for Dermagraft and TransCyte. The product is then developed to meet the design requirements

**Table 79.1. Design concepts for Dermagraft and TransCyte****Dermagraft**

- Dermal replacement, later as a cytokine factory
- Allogeneic
- Viable product
- No sterile fill; i.e., bioreactor would be package
- Long shelf life (~6 months)
- Suitable size
- User-friendly presentation — modified bag

**TransCyte**

- Transitional covering for third-degree burns to replace cadaveric skin
- Allogeneic
- Nonviable
- No sterile fill; i.e., bioreactor would be package
- Long shelf life
- Suitable size (from Biobrane size)
- User-friendly presentation — clamshell bioreactor

by a series of hierarchical, more and more detailed design processes that ultimately comprise the *design master file*. The requirements can be divided into groups. In each case, the first statement is concerned with the therapeutic purpose of the product, the next three describe intrinsic characteristics of the product, and the last three are concerned with practical issues of importance to the final user. All these factors need to be considered from the earliest stages of development.

### Overall Concept

The initial application for Dermagraft was a dermal replacement for burn patients. Initial clinical application indicated that it provided little benefit and was slightly deleterious. As trials for chronic-wound applications progressed and it became evident that it was efficacious, the concept of Dermagraft as a cytokine source replaced the notion of a dermal replacement.

TransCyte, a replacement for cadaveric skin for covering third-degree burns after debridement, was seen as a means to overcome problems with rejection and potentially with disease transmission.

### Allogeneic Cell Source

The second item in both product concepts was that the products be allogeneic. The decision whether a product will be allogeneic or autologous is fundamental to the entire development process. While not impossible, the development of a commercially successful (profitable), autologous tissue-engineered product is very difficult. It requires separate, independent tissue culture suites (hood, incubator,

centrifuge, microscope, and air conditioning), which will be occupied by a product for a single individual for the entire period of culture. It is a service industry, with complex logistics and high cost. As an alternative, it would be possible, in principle, to construct an automatic machine that would accept a patient's tissue and produce the tissue-engineered construct in the hospital, with minimal intervention. An advantage to an autologous process is the comparatively low requirement for safety testing and the lack of immunological rejection by the patient.

Allogeneic tissue engineering has advantages in using only one tissue culture facility per product type, allowing economies of scale and straightforward logistics. The major disadvantages are the very large amount of safety testing required for the master cell banks and the potential for immunological rejection. The first of these disadvantages is ameliorated by the infrequency of making master cell banks. In the case of Dermagraft and TransCyte, one master cell was used for 15 years, so the investment could be amortized over a long period. Testing is determined by regulatory authorities from time to time, but it includes testing of the donor and, in the case of fibroblasts, the donor's mother for major human pathogens (HIV, hepatitis, CMV, etc.), xenogeneic pathogens, karyotype, identity (isoenzyme, VNTR, SNP, etc.), tumorigenicity, latent viruses, etc. This is tested both on the initial Master Cell Bank and again on cells reisolated from final product (the *end-of-production cell bank*).

### Viability of Product and No Sterile Fill

The viability of the product depends on its intended function and differs for Dermagraft and TransCyte. As discussed later, to package sterile material is a matter of some difficulty, and it was decided to avoid the issue. The bioreactor in which the tissue was grown was designed to form part of the final packaging.

### Shelf Life

Extended stasis preservation is important for commercial products, including tissue-engineered products. It allows time for quality control testing, for off-the-shelf availability, and for distribution. In addition, the Dermagraft and TransCyte processes take 12 weeks, from thawing a vial from the *manufacturer's working cell bank* (MWCB) to cell expansion, three-dimensional growth, and QC testing. The difficulty of predicting the market so far ahead so as to minimize waste is greatly aided by extended shelf life. This was achieved through cryopreservation at  $-70^{\circ}\text{C}$ .

### Size, User Convenience

The remaining items in the product concept are related to convenience of use by the physician applying the product. This is an important item for a commercial product and needs much work in focus groups and thought. Thawing the product is already a major issue, requiring time and, in the case of TransCyte, careful estimation of the amount required,

to avoid wasting expensive material or having to wait for a piece to be thawed. The Dermagraft bioreactor was designed so that it would open easily and the tissue would be positioned (through the use of a Z-weld that attached opposite sides of the scaffold to opposite walls of the bioreactor) so as to be easily rinsed prior to use. The bioreactor is translucent, to aid in marking the piece to be cut out for implantation.

## V. MANUFACTURE OF DERMAGRAFT AND TRANSCYTE

Overall schemata for the manufacture of Dermagraft and TransCyte are illustrated in Fig. 79.1. As can be seen, as much of the two processes as possible are identical. This economizes resources and reduces cost. In this case, the MCB, MWCB, the cell expansion process, and much of the release testing are all in common. In addition, the clean-room facility, all its ancillary equipment, and monitoring are the same.

The process overall takes about three months, from MWCB vial to releasable product. This makes the availability of shelf life through cryopreservation of particular importance to provide a buffer to minimize wastage or loss of supply.

### Cells

Several times per week, fibroblasts used in manufacture are recovered from liquid nitrogen storage (the MWCB) and expanded in roller bottles from the fifth to the eighth passage. This is a conventional procedure but may not be ideal. Fibroblasts for Apligraf are expanded on beads in a mixed bioreactor. It has become evident that the proliferation of fibroblasts is improved at low oxygen (2–6%) (Falanga and Kirsner, 1993), and, at this oxygen concentration, the development of a senescent phenotype may be reduced (Busuttill *et al.*, 2003; Parrinello *et al.*, 2003; Chen *et al.*, 2004). A tank bioreactor lends itself to active control of parameters

such as oxygen tension and pH and is worth exploring before a system gets fixed by regulation. The cells ideally should be grown just to the beginning of stationary phase. Further incubation seems to be slightly deleterious.

### Medium

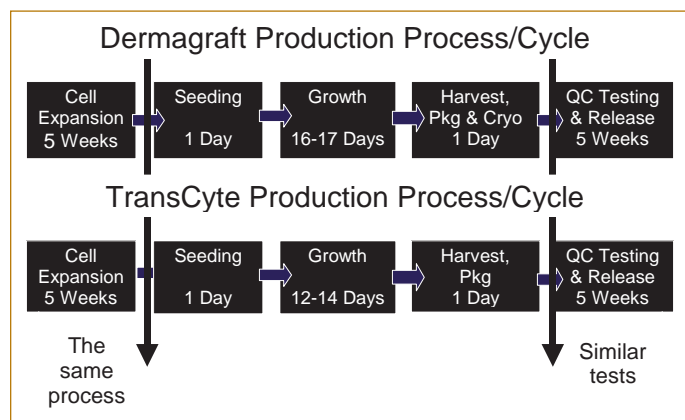

The Dermagraft and TransCyte systems are grown in Dulbecco's-modified Eagle medium, supplemented with 10% calf serum, nonessential amino acids, and glutamine. All tissue culture beyond initial cell isolation from the foreskin is free of antimicrobial agents. Antimicrobial agents might hide otherwise significant contamination, which might only become evident in therapeutic application.

While serum-free medium is available for keratinocytes, it has been found difficult to achieve such systems for fibroblasts. With the increased concern about the transmission of prion diseases, there has been great interest in developing serum-free systems. Serum-free fibroblast media are commercially available, but while these have been successful in the research laboratory, transferring them to scaled-up systems and manufacturing has proved elusive. The major issue is that the cells do not grow to the extent required, apparently because, early on, they acquire a senescent phenotype. It was early established that serial subculture of fibroblasts leads to senescence after about 60–80 population doublings. While this can be attained in serum-containing medium, experience with serum-free media have indicated a life span of about nine doublings. Since Dermagraft is made at about the 28th generation, about 10 doublings from the MWCB, 19 from the MCB, and implanted fibroblasts should not be too close to senescence, serum-free media do not provide sufficient proliferation potential.

The alternative solution to serum-free medium is to take extreme caution in the source and treatment of serum. By regulation, all materials used in manufacture must be traceable to their sources. But, in addition, bovine serum is obtained only from countries that are free from bovine spongiform encephalopathy (BSE), which includes Australia and New Zealand, from closed herds with a known pedigree history that includes no animals from outside the country. Serum is also irradiated sufficiently to eliminate possible viral contamination.

### Bioreactor Design

Many of the considerations of bioreactor design involve questions of mass transport, conditions under which cells are able to grow, and so forth, much as in noncommercial tissue-engineering systems. A second series of considerations deals with the large-scale production process. These include ease of scale-up, ease of handling, minimal footprint, and maximal automation. In addition, the use of the product by a community not experienced with products of this type is also important. This leads to features to make the product easy for the end user to work with and apply.

**FIG. 79.1.** Overall comparison of the Dermagraft and TransCyte processes.

The bioreactor used for the growth of Dermagraft consists of a bag with eight cavities welded into it, each of which contains a sheet of the scaffold. Such bags are attached in groups of 12 to manifolds, with a solid support, for cell, medium, or cryopreservative addition, to form a system. Several systems may be connected and all fed at the same time to form a lot, which is the unit of manufacture. The bag reactors, systems, and even lots may be assembled under clean but not necessarily sterile conditions and sterilized by 25–43 grays gamma-radiation prior to seeding. From this point, the process requires only nine sterile connections and is substantially automatic.

The TransCyte bioreactor systems are similarly assembled under clean conditions, complete with all associated tubing, and attached in groups of 12 to a manifold to form a system. This entire assembly is then sterilized by gamma radiation, as just described. Several systems can then be connected to form a lot. In this case, the inlets to each bioreactor are individually passed through a peristaltic pump to provide even flow. (Attempts to use constrictions to control flow was found to be inferior.) Again, as with the Dermagraft system, once set up and seeded, the TransCyte system is substantially automatic.

Automation in tissue-engineering systems is an important feature. Apart from reducing labor costs, automation greatly reduces the number of errors that have to be investigated, requiring time, effort, and cost. While operator errors are generally less serious than machine failures, they are much more numerous and still require individual investigation. Backup systems can be installed to minimize the impact of machine failure.

## VI. DERMAGRAFT AND TRANSCYTE PRODUCTION PROCESSES

The production of Dermagraft and TransCyte started with the cryopreserved master cell bank, which was stored at passage 3 in liquid nitrogen. About four times per year, cells were taken from this bank and expanded in roller bottles to fifth passage, when they were stored again as the MWCB. This was tested to ensure identity to the master cell bank. Several times per week, cells are taken from the MWCB and expanded to eighth passage in roller bottles, when they are seeded to the three-dimensional bioreactors. This process is conventional, large-scale tissue culture. It uses batch feeding and exposes the cells frequently to atmospheric oxygen. As discussed elsewhere in this chapter, fibroblasts grow better and senesce less rapidly in a lower-oxygen environment. Experiments have been conducted to expand the fibroblasts on beads in tank bioreactors, which allow both control of such variables as oxygen tension and pH as well as continuous feeding.

On seeding, the bioreactors are manipulated to ensure even distribution of the cells. In the case of Dermagraft, the bioreactors are rolled; in the case of TransCyte, each side is

seeded successively under static conditions. The medium is replaced one day after seeding, and then the cells are fed every two to four days until harvest.

The time of harvest is determined from the glucose metabolism of the cultures. In the case of TransCyte, glucose consumption and lactate production are determined daily and interpreted as notional ATP turnover, assuming a P : O ratio for mitochondrial oxidative phosphorylation of 3. The resulting values are correlated with the performance of the system relative to release specifications and appropriate target values selected. In the case of Dermagraft, there was a concern that lactate release from the degradation of the scaffold might interfere with the ATP turnover estimation, so the time of harvest was determined on cumulative glucose utilization alone.

At harvest of Dermagraft, medium is replaced by cryopreservative solution, which consisted of 10% dimethylsulphoxide in phosphate-buffered saline, supplemented with calf serum, and the individual pieces of Dermagraft are sealed, removed from the surrounding bag, packaged, cooled slowly at a rate that fell within design parameters, and frozen. It is then stored in a freezer set to  $-75^{\circ}\text{C}$ . The time between cryopreservative addition is at least 4 h and is validated to a 12-h delay. This time interval did not appear to affect the viability of the cells, and it was conjectured that it allowed induction and synthesis of stress proteins in response to the high osmotic pressure.

### Release Specifications

The release specifications include sterility for bacterial, fungi, mycoplasma, and endotoxin as well as for analytical criteria that ensure consistency of the product. Dermagraft uses four analytical release criteria: MTT reductase activity before freezing (in-process MTT), and after thawing, collagen content by Direct Red binding (Bedossa *et al.*, 1989) and DNA content. MTT reductase was used to determine the metabolic activity of the product, collagen as a surrogate for the amount of extracellular matrix, and DNA content was used to establish adequate cellular content. MTT reduction was an assay established early in the development of Dermagraft. Since then, several other substrates measuring essentially the same activity have been developed, several of which are less toxic to the cells than MTT and can be used repeatedly. It would be wise in the development of a new product to examine these early and select a method carefully. MTT reductase is frequently viewed as measuring mitochondrial activity. However, 70% of the activity is extramitochondrial (Musser and Oseroff, 1994), and it is better regarded as a general measure of cellular activity. The MTT reductase assay was originally developed to evaluate toxicity or cell proliferation, where values obtained after treatment were compared with control values. In determining the metabolic activity of tissue-engineered products, this is not possible, and a great deal of fruitless effort has been expended trying to obtain a standard for the MTT assay.

MTT determination before and after cryopreservation might be interpreted this way. However, changes occur in the viability and metabolic activity of cells for up to three days after cryopreservation, due to necrosis, apoptosis, and repair, so the MTT values are better regarded as independent absolute determinations than as relative values.

In the case of TransCyte, the microbiological criteria and the collagen and DNA determinations are similar to those for Dermagraft. However, because the cells are nonviable in the final TransCyte product, there is no MTT determination. Determination of MTT reductase prior to final freezing (in process MTT) was replaced by release specifications applied to ATP consumption, as described earlier.

Definition of specifications was initially within three standard deviations of the process performance. This was refined by clinical experience. In the case of MTT, it was evident during the clinical trial that the specifications needed to be refined, requiring a midtrial correction and ultimately an additional clinical trial.

### Distribution and Cryopreservation

The use of  $-70^{\circ}\text{C}$  cryostorage for Dermagraft was a compromise between an ideal solution and practicality and turned out to have several benefits. If the goal was 100% cell viability and indefinite shelf life, the ideal solution would probably have been storage at liquid nitrogen temperatures, probably using a vitrification procedure in which high concentrations of cryoprotectant and very rapid cooling are used to achieve the formation of a glass with minimal ice crystallization. While the technical difficulties of achieving sufficiently rapid cooling of a therapeutically useful structure and problems with the brittleness of plastics at low temperatures can probably be overcome, the method would still entail transport at liquid nitrogen temperatures and safety issues. Cryopreservation at dry ice temperatures provided adequate shelf life and allowed shipping in a container capable of maintaining  $-65^{\circ}\text{C}$  for four days. This allowed distribution throughout the world and would generally permit two to three days of leeway for patient and physician scheduling at the site of use. If a center had a  $-70^{\circ}\text{C}$  freezer, storage at this temperature would result in much longer shelf life.

In addition, the induction of stress proteins by the cryopreservation procedure (K. Liu *et al.*, 1998), combined with the suboptimal viability recovery, meant that necrotic cell debris, including heat shock proteins, were released from lysed cells. Such proteins activate macrophages through CD91 and possibly toll-like receptors (Curry *et al.*, 2003). While such necrotic products are likely not scarce in a chronic wound, this property may have contributed to the efficacy of Dermagraft.

While discussing cryopreservation, an important point that has received little attention is the thawing process. In the case of Apligraf, the thawing process involved solutions

that had to be replaced, requiring a procedure of several hours, which was performed at the company. This provided shelf life but not off-the-shelf convenience and required additional resources from the company. Therefore, the procedure was not continued. In the case of Dermagraft, thawing is performed in the physician's office, out of the control of the company.

During the controlled freezing process, after the majority of the osmotic water removal has occurred, the cell contents reach a eutectic and freeze. While the majority of the material forms a glassy state, small ice nuclei may be formed. The slow growth of these nuclei during  $-70^{\circ}\text{C}$  storage is probably what limits shelf life. During thawing, conditions arise that allow the growth of ice crystals, the nuclei enlarge and, if they become big enough, will kill the cells. It is important to take the cells through this stage as rapidly as possible to minimize growth. So rapid thawing, straight from the  $-70^{\circ}\text{C}$  storage, is critical. The procedure that was adopted involved a thawing tub with a thermometer, which could be filled with warm water from the tap or a water bath at  $37^{\circ}\text{C}$ . A few seconds unprotected in ambient air was sufficient to reduce viability drastically.

### Problems with Commercial Culture for Tissue Engineering

In large-scale tissue culture, procedures are followed that differ from those found in a research laboratory. As a result, problems have arisen from time to time that have no counterpart in culture on a smaller scale. Frequently, it is difficult to establish the cause unequivocally because of the scale and cost of the experiments that would be required. When such a problem occurs, it is usual to assemble all those with potentially valuable ideas, analyze the incident with respect to changes in procedure (new batches of medium or other raw materials, newly implemented changes, etc.), and prioritize possible solutions. Usually the most likely and cheapest suggestions are explored. Such suggestions are frequently implemented more or less at the same time and immediately. When the problem ceases, as it usually does, it is very difficult to determine which suggestion solved it. At best, there is a reasonable rationale.

Examples of such occurrences include light damage to medium and deterioration of cell banks. It has been known for many years that medium is light sensitive and will degrade if left exposed to daylight or fluorescent light. However, such an event is never seen in the research laboratory, because medium is normally stored in a refrigerator in the dark. In commercial operation, it is sometimes necessary to make up medium a few weeks in advance and to store it in a cold room. If the lights in the cold room are fluorescent and are left on, deterioration of medium will be observed. Indeed, the Dermagraft plant was illuminated with yellow light to avoid such problems.

In a research laboratory, cells stocks frozen in liquid nitrogen are manipulated rarely, a few times per year. In

commercial-scale tissue engineering, vials from the MWCB are removed several times per week. While one or two vials are identified and removed, the remainder is out of cryostorage and warming up. We noticed that, after some years of this, the fibroblasts could be shown to demonstrate a decreased life span. This was attributed to ice recrystallization during periodic warming to perhaps  $-120^{\circ}\text{C}$  to  $-90^{\circ}\text{C}$  during recovery of other vials. It is, thus, necessary to store the MCB independent of the MWCB and to devise a method of recovering selected vials with minimal disturbance to other vials.

## VII. CLINICAL TRIALS

The design and implementation of clinical trials is specialized and beyond the scope of this discussion. The process requires a great deal of time and expense. In the case of the CDRH division of the FDA, the initial trial is a pilot, or feasibility, trial, equivalent to a phase 1 trial in the CBE or CDER. This consists of a small number of patients (6–20) per treatment regime and is concerned primarily with safety. Any information obtained on efficacy in a trial of this magnitude is unlikely to be statistically significant but may provide useful information on the size and variability of the therapeutic effect that is valuable in design of the subsequent, pivotal trial.

The pivotal trials (equivalent to phase 2 trials in biologics and devices) involve much larger numbers of patients (50–500 in the case of devices), which are determined by a sample-size calculation, based on the results from the pilot trial, to give about 80% probability of a significant result ( $p < 0.05$ ) if one exists.

Trials with chronic wounds take about two years or more to complete. The design phase — deciding on protocols, obtaining institutional approval for multiple centers, and preliminaries to the recruitment of patients — is likely to take at least six months. The actual trial involves screening many more patients than will actually take part in the trial, for many fail to conform to exclusion criteria, which reduce irrelevant and interfering factors, established in the design phase. With a trial involving a 12-week follow-up period, most should be completed within 18 months to two years. There is then a period of six months while the data are checked, discrepancies resolved, and the results of the trial evaluated. This period could be shortened substantially by logging the patient outcomes and checking them online as they are generated.

The design of the clinical trial should be conducted in close consultation with the relevant regulatory authorities. It is critically important that all aspects be thoroughly discussed and agreed on beforehand. In the case of Dermagraft, failure to follow advice from the FDA precisely led to considerable delay and additional expense.

Considerations in the selection of clinical trials include the size and value of the potential market, the expected efficacy of the product, and the difficulty of completing the

trials. Five major areas of chronic wounds include venous stasis ulcers, diabetic foot ulcers, arterial ulcers, pressure (decubitus) ulcers, and all other chronic wounds. Of these, venous stasis ulcers represent the largest market. Diabetic ulcers are a valuable market, because, while smaller in number, the consequence of failure to heal such an ulcer is limb amputation, an expensive and seriously debilitating procedure. It is very difficult to perform a trial on decubitus ulcers, because the patients are frequently elderly and very infirm and may need approval from a guardian. Such trials are arduous, may be difficult to complete, and are best undertaken by a specialized group with well-developed access to such patients. In no cases does the treatment of chronic wounds with skin implants address the underlying cause of the ulcer, which lies in venous insufficiency, metabolic abnormalities, reduced arterial supply, or repeated ischemia. This is particularly evident in ulcers caused by arterial insufficiency. While the angiogenic activity implant may be capable of improving vascularity in the region of the wound, little may be gained if blood supply to the limb is inadequate.

The pivotal clinical trial for Dermagraft for diabetic ulcers was initiated in 1994. Dermagraft gave a statistically significant increase in healing of 19.1% that was similar to results obtained in similar trials with other products. These data were used in combination with mechanism of action and clinical instruction to support the clinical use of Dermagraft commercially.

The indications for which the product may be marketed (its labeling) are strictly limited by the clinical trials, and new trials are required to extend them. However, in certain categories, there may be an insufficient number of patients to support both a clinical trial and a commercial market. Examples are monogenetic congenital diseases, where, although the conditions may be very distressing, the entire population may number in the hundreds or a few thousand. An example in the chronic-wound field is epidermolysis bullosa (EB). For such diseases, the FDA has a category, Humanitarian Device Exemption (HDE), which allows much reduced clinical testing. It does, however, require Institutional Review Board (IRB) approval from each institution where it will be used. In the case of dermal implants, such a route has been used for Apligraf and OrCELL for all genetic forms of EB and for Dermagraft for the dystrophic forms of EB. The category of “all other chronic wounds” includes many miscellaneous conditions, such as pyoderma gangrenosum and necrobiosis lipoidica diabetorum, for which there is too small a patient population to perform a trial but that would be expected to benefit from treatment with Dermagraft or TransCyte. The HDE pathway may not be appropriate or available. However, since the FDA does not regulate the practice of medicine, some approach to these patients may be obtained through off-label use, although this cannot be formally promoted by the manufacturer.

## VIII. IMMUNOLOGICAL PROPERTIES OF TISSUE-ENGINEERED SKIN

Immunological rejection of tissue-engineered products is, at the time of writing, a controversial question. As was clearly established by Medawar in the 1940s, allogeneic transplants of whole live organs invariably cause immunological reactions that lead to rejection (Medawar, 1957). However, experience with some cultured cells and tissue-engineered constructs indicates, in some cases, no clinically significant rejection. At this point, some 90,000 pieces of Dermagraft have been implanted, in many cases several times to the same patient, without a single example of immunological rejection, and experience with Apligraf has been similar. The fibroblasts from Dermagraft have been found to persist in the wound site for six months, and survival for about a month has been obtained with Apligraf (Phillips *et al.*, 2002).

There are two major pathways of transplant rejection, direct and indirect. The direct pathway involves recognition of donor histocompatibility antigens (HLA) by the host immune system, leading to acute rejection over about two weeks. This involves both HLA, of which Class II molecules, such as HLA-DR, are the most important, and costimulatory molecules on the transplant, the CD40 and the CD80 groups. These molecules are not normally expressed by fibroblasts. However, in monolayer tissue culture, the presence of  $\gamma$ -interferon, which may be present in chronic wounds, will cause induction of HLA-DR, CD-40, and genes involved with the physiological function of class II HLA (antigen presentation). In three-dimensional culture, many of the cells show a selective response to  $\gamma$ -interferon, which does not include induction of these molecules (Kern *et al.*, 2001). The indirect pathway of rejection involves display of transplant antigenic peptides by host antigen-presenting cells (macrophages, tissue dendritic cells, and endothelial cells). This gives rise to chronic rejection, which may cause destruction of the transplant over many months. While it cannot be excluded that this might occur, Dermagraft fibroblasts have been detected at six months from the time of implantation, and no clinical evidence for chronic rejection has been observed.

Acute rejection is primarily an attack on the endothelial cells of the vascular system, which are antigen-presenting cells and do express the component of the antigen presentation system (HLA Class II, CD40, CD80). It is possible that the lack of rejection of tissue-engineered skin products is related to the absence of such cells. Indeed, adding antigen-presenting cells (in this case, B-lymphocytes) to a tissue-engineered construct has restored susceptibility to immunological rejection (Rouabhia, 1996).

## IX. COMMERCIALIZATION

There are many contributors to the commercial success of a product. They include a satisfactory clinical trial, a good

rationale for the performance of the product, convenience in use, a reasonable price, adequate reimbursement from third-party payers, sensitivity to complaints, and efficient distribution. Some of these require long-term effort and must be initiated early in the development process.

New products frequently find themselves selling into a conservative and skeptical market that arises from the hype involved in developing and funding the product. The first requirement in overcoming this view is a satisfactory clinical trial. This process is determined by regulatory bodies and is outside the scope of this chapter. However, the major criteria for the American authorities (FDA) are safety and efficacy. Unless the product is safe and efficacy is extraordinary, clinical results need to be backed up by a mechanism of action that, while it may not be fully established, must provide a logical reason for using the product. In the case of Dermagraft, this has led to a great deal of fundamental wound-healing research.

Equally important is the convenience of use, the cost, and the process for reimbursement of the physician applying it. Convenience of use and cost are functions of bioreactor and process design and company structure and are discussed elsewhere. Third-party reimbursement and health economics are major and specialized subjects that are outside the scope of this chapter. However, a major component of establishing satisfactory reimbursement in the United States involves the Center for Medicare and Medicaid Services (CMS). Government authorities with similar responsibilities are involved in other countries. Their criteria, in contrast to those of the FDA, are reasonableness and effectiveness/cost ratio. Both the FDA-type and CMS-type criteria have to be met for a product to be successful.

An activity that would prove very valuable in establishing the performance of a product is a system for tracking the clinical performance subsequent to regulatory approval to market the product. While complaints and adverse events are carefully tracked and reported, performance has not been. It may, however, become a regulatory requirement to confirm safety, efficacy, and cost effectiveness with a larger patient population than possible in a clinical trial. It is also valuable to the manufacturer because, while anecdotes of positive clinical experience may be heartening, they do not provide objective quantitative data. This was not performed in the cases of Dermagraft or TransCyte, making it difficult to assess the actual performance of the product in clinical use.

### Mechanism of Action

Understanding the mechanism of action of a product requires some understanding of the underlying pathology of the disease the product is intended to treat. Wound healing, and particularly the etiology and maintenance of chronic wounds, was poorly understood during the development of Dermagraft and TransCyte. Many phenomena have been observed, particularly in chronic wounds. The

problem is sorting out how they relate to one another, i.e., which are etiological and which symptomatic, the difference between cause and response. The problem was less acute in the case of TransCyte because the product was designed as only a temporary covering for third-degree burns.

Changes from normal skin observed in chronic wounds include lack of keratinocyte migration, capillary cuffing, protease activity, abnormalities in macrophage activation, diminished vascular supply, and senescence in fibroblasts (Agren *et al.*, 2000). In developing a rationale for the action of Dermagraft, the first aspects considered were vascular supply and keratinocyte migration. Much study was undertaken on the angiogenic activities of Dermagraft, and it was shown that the tissue produced VEGF and hepatocyte growth factor. It was also shown to be angiogenic in the chick chorioallantoic membrane assay and to increase blood supply to diabetic ulcers in patients *in vivo* using laser-Doppler techniques. Thus, a case could be made that one mode of action was through its angiogenic effect.

The high protease activity of chronic wounds was combined with the lack of keratinocyte migration to hypothesize that the extracellular matrix in a chronic wound was degraded to the extent that the migration substrate was lacking. Indeed it was demonstrated that fibronectin was degraded by neutrophil elastase (Grinnell and Zhu, 1996). This led to work on the properties of Dermagraft and TransCyte as substrates for keratinocyte migration.

During comprehensive surveys of genes induced by three-dimensional culture, it was found that the most highly up-regulated gene was IL-8. Other ELR CXC chemokines were also highly induced. This led to studies of the secretion of these proteins and to changes in their production that might relate to the etiology of chronic wounds and the possible role of Dermagraft. It was found that Dermagraft secretes IL-8, sometimes in large quantities. The secretion is extremely variable. Monolayer fibroblasts also secrete CXCL-1, CXCL-5, and CXCL-6 (gro- $\alpha$ , ENA-78, and GCP-2, respectively), which are all chemoattractive for neutrophils and activate them to a bactericidal phenotype. At the same time, it was observed that bacterial products (lipopolysaccharide) inhibit keratinocyte migration. This led to the hypothesis that a major function of fibroblasts in a wound context is the recruitment of neutrophil leukocytes to destroy colonizing bacteria and that failure of this system in chronic wounds results in the establishment of bacterial contamination that leads to failure of re-epithelialization. It is known that fibroblasts in chronic wounds display a senescencelike phenotype (Raffetto *et al.*, 1999) that grows slowly and is unresponsive to growth factors. The condition is probably related to stress-induced premature senescence caused by ischemia reperfusion injury, metabolic abnormality, extravasated red cells, and the inflammatory conditions of the chronic wound. It has been found that the production of CXCL-1, CXCL-5, CXCL-6, and CXCL-8

declines in senescent fibroblasts. Thus, in chronic wounds, a decline in the ability of the fibroblasts to recruit and activate neutrophils allows wound colonization by bacteria and failure of keratinocyte migration to close the wound. Chronic wounds seem to involve an arrest of normal healing at about the stage of neutrophil immigration. On this hypothesis, a major role of Dermagraft is to provide nonsenescent fibroblasts that are able to respond to the presence of bacteria with appropriate secretion of neutrophil chemoattractant chemokines.

In the case of TransCyte, the formation of a foreign-body capsulelike material *in vitro* leads to lack of ingrowth of the scaffold into the wound through a host foreign-body reaction and, thus, comparative ease of removal. The ability of TransCyte to reduce the pain of second-degree burns is common to many occlusive dressings.

A remarkable feature of dermal implants is that they do not appear to have led to an increase in infection. Indeed the general experience has been a slight reduction in infections. Preparations with keratinocytes included secrete antimicrobial peptides, but this is not known to be the case for fibroblasts. The most likely explanation is a combination of fibroblast secretion of neutrophil chemoattractant CXC chemokines and the provision of an extracellular matrix substrate for leukocyte migration.

## X. FUTURE DEVELOPMENTS

The major direction of development in skin products is toward simpler, possibly nonviable systems. Inclusion of live cells in a product entails many issues, such as the use of allogeneic cells, cryopreservation, distribution, inconvenience to the customer (for instance, the thawing procedure), and many manufacturing problems. Hence, studies were initiated to explore the possibility that a somewhat less effective but substantially less expensive product could be developed. This is a direction that has also been explored by other companies in the field.

It is a general principle that value is likely to be obtained by exploiting a technology base as far as possible. A major product of fibroblasts is collagen, in this case human. As a nonviable product, human collagen was extracted from the extracellular matrix laid down by fibroblasts and used, by injection, for the treatment of wrinkles.

An alternative to cryopreservation that has been explored is the possibility of storage by desiccation. Many natural systems, such as plant seeds, tardigrades, *Artemia*, and yeast, have developed the ability to survive desiccation and, in that state, may be able to survive extreme conditions of temperature, vacuum, radiation, and time (Crowe and Crowe, 2000). Many factors appear to be involved in this ability (Mattimore and Battista, 1996), but one that has attracted attention is trehalose, which is a disaccharide (1,1, $\alpha$ , $\alpha$  diglucose) that is produced in large quantities by many desiccation-resistant organisms. It was found that TransCyte could be dried at room temperature in the

presence of trehalose and irradiated to 25–40 grays to provide terminal sterilization, and it would recover its structure and wound adhesion on rehydration. Similar results could be obtained by careful lyophilization. While some success has been obtained in the retention of viability of human cells in the desiccated state, it is not yet possible to obtain the shelf life (at least one month and preferably at least six months) required for a tissue-engineering application. It is also questionable whether the radiation treatment possible with a nonviable product would be appropriate with living cells, and an aseptic drying-and-packaging system would have to be devised.

Thus far, the therapeutic applications of skin-tissue engineering have encompassed acute and chronic wounds and comprise dermal components alone or dermal components with epidermal structures. In the future, it is likely that adnexal structures will be added. Remarkable success in this direction has been achieved with hair follicles (Zheng *et al.*, 2005), where it has been found that hair follicle-inducing cells can be cultured so that they retain their properties and, mixed with hair follicle-derived keratinocytes, will, on injection, form a hair. The remarkable feature of this system is that the entire organ is formed: hair follicle, sebaceous gland, and erector pili muscle. This constitutes one of the few examples of true organogenesis observed using adult cells.

## XI. CONCLUSION

Experience with the commercial production of tissue-engineered skin has developed many principles that are

important beyond the simple development of a tissue-engineered product. Most of these are based on well-known concepts used in other manufacturing processes but applied to tissue engineering. They include:

1. Optimized cryostorage of master cell banks with minimal access
2. Intermediate storage of expanded cell banks (MWCB)
3. Use of allogeneic cells
4. Bioreactors that permit scale-up and minimize footprint
5. Minimal aseptic connections
6. Maximal automation, to minimize errors
7. Avoidance of aseptic fill so that the bioreactor forms part of the final package
8. Bioreactor designed for end-user convenience
9. Cryostorage

While it may not be possible to incorporate all of these principles, as many as possible should be used. The major problem with tissue-engineered products in the marketplace is cost, and all these principles are directed toward reducing cost. Some, such as the use of allogeneic cells, may be difficult to implement. While experience with fibroblasts indicates that immunological rejection is not a major issue, this is not known for other cells. The possible use of allogeneic cells should, however, be checked, preferably in animals other than mice, because the advantages for a commercial product are great. Optimal cryostorage is a compromise between ideal tissue survival and other factors, such as ease of distribution.

### I. INTRODUCTION

Repair of damaged articular cartilage has been a long-standing clinical challenge. This is an area in which we have made significant clinical progress since the second edition of this textbook. This progress includes an improved understanding of the spectrum of cartilage injury and comorbid conditions, development of treatment algorithms, long-term experience with first-generation autologous cultured chondrocyte cell-based repair, early experience with second-generation autologous cultured chondrocyte cell-based repair, and improved methods for clinical evaluation both in practice and research settings.

The challenges of articular-cartilage repair relate to both the biologic characteristics of the tissue and the epidemiology of cartilage injury. Articular cartilage lacks intrinsic capacity for repair. The clinical strategy for autologous cultured chondrocyte cell therapy derived from the observations that articular cartilage is avascular and has a limited supply of cells adjacent to injuries to mediate a repair process (McPherson and Tubo, 2000). The articular chondrocytes that maintain normal cartilage homeostasis are embedded in an extracellular matrix that limits a cell's ability to migrate to a zone of injury and that repair it with normally functioning tissue.

Articular-cartilage injuries are common, especially in the knee, and are often associated with damage to other joint structures. There is a spectrum of clinical presentations, ranging from some lesions that may be asymptomatic on initial diagnosis, often in the setting of an incidental finding during an arthroscopy initially indicated for another more evident injury, to lesions that may cause disabling symptoms. The public health impact of these latter types of lesions is magnified because they often occur in relatively young adults and may progress to end-stage arthritis. There clearly is a subset of patients with articular-cartilage injury that are very disabled. For example, preoperative baseline overall condition in a series of patients, mean age 37 years, treated with autologous chondrocyte implantation (ACI) was noted to be a mean of 3.2 on a 10-point scale, indicating poor function with "significant limitations that affect activities of daily living" (Browne *et al.*, 2005).

Although the incidence and prevalence of symptomatic full-thickness chondral injuries in the general population have not been established, it is known that cartilage lesions are a common finding at knee arthroscopy. Curl *et al.* (1997) reviewed records from 31,516 knee arthroscopies and reported Outerbridge Grade III cartilage lesions in 41% and Outerbridge Grade IV lesions in 19%. They reported an

**FIG. 80.1.** Illustrative example of current treatment algorithms for repair of symptomatic cartilage lesions. The algorithm gives an overview of treatment options based on lesion size, patient functional demands, and prior surgical history. Given other factors and the complexity of decision making for individual patients, the authors of this algorithm caution against a mechanistic “menu-driven decision-making process.” D&L = debridement and lavage; MST = marrow stimulation technique; Auto OCG = autologous osteochondral graft. Reproduced with permission from Cole and Farr (2001).

**FIG. 80.2.** Choosing the most appropriate and optimal cartilage repair treatment for an individual patient depends on multiple factors.

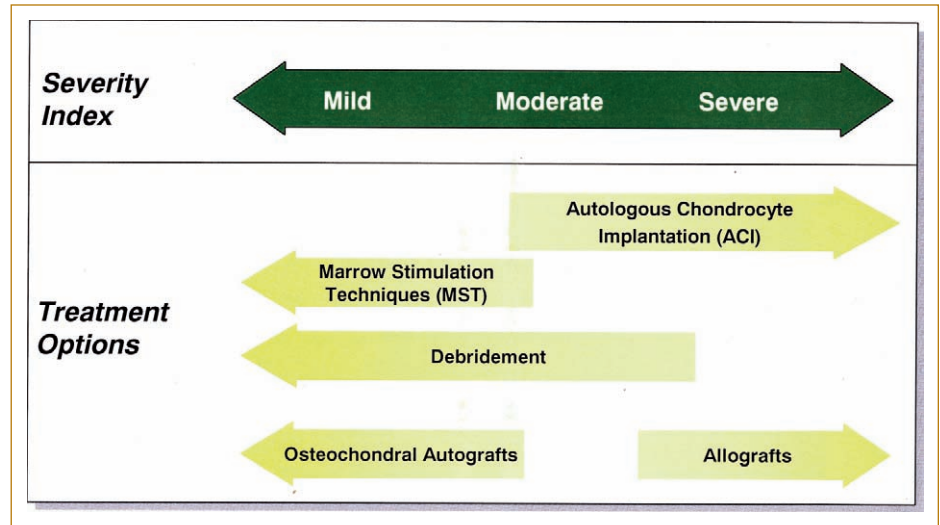

incidence of 5% Grade IV lesions when considering only lesions on the femoral condyle in patients less than 40 years old. Other authors have reported a similar incidence of full-thickness cartilage lesions in other arthroscopy series (Hjelle *et al.*, 2002; Aroen *et al.*, 2004).

Cartilage injury in the knee is often associated with other injuries, especially anterior cruciate ligament (ACL) rupture, meniscus tears, and patella dislocation (Maffulli *et al.*, 2003; Tandogan *et al.*, 2004; Nomura *et al.*, 2003; Nomura and Inoue, 2004 ). For example, Maffulli *et al.* reported that 42% of patents in a series of 378 patients with ACL tears had associated articular cartilage injuries (Maffulli *et al.*, 2003). In a multicenter registry of 1095 knee cartilage injuries, the etiology of the injury was associated with falls (25.9%), sports (27.4%), activities of daily living (21.2%), and motor vehicle accidents (5.5%), and the etiology could not be identified in 20% of cases (*Cartilage Repair Registry Volume 7*, 2001). In this same study, the onset of symptoms was noted to be acute in 64.6% of cases and gradual in 35.4% of cases. Another distinct etiology for articular cartilage lesions is osteochondritis desssicans (OCD) (Wall and Von Stein, 2003; Micheli *et al.*, 2006).

Since the mid-1990s, treatment algorithms have evolved that reflect the range of cartilage lesion presentations, the different indications for different treatment modalities, and the outcome data (Minas, 1999; Cole and Farr, 2001; Scopp

and Mandelbaum, 2005). While these algorithms may differ in specific detail, they are directionally similar and base treatment guidelines on such factors as lesion size and location, prior surgical history, and patient expectations and functional demands. Figure 80.1 is provided as an illustrative example of current treatment algorithms (Cole and Farr, 2001). Clinical decision making for a given individual patient can be complex, and the multiple factors to evaluate and consider are outlined in Fig. 80.2. In decision making for treatment of articular-cartilage lesions, it is critical to consider the whole joint and the whole patient and not just the hole in the articular cartilage surface.

While it is beyond the scope of this chapter to review the outcome literature for all articular-cartilage treatment modalities, it is helpful to understand where traditional first-line arthroscopic treatments and the cell-based tissue-engineering experience fit in current treatment algorithms. In general, first-line arthroscopic treatments are used in less severe lesions, and autologous chondrocyte implantation is used in more severe lesions (Fig. 80.3). The impetus for developing ACI came from the recognition that while traditional treatments such as debridement and marrow stimulation techniques (Priddie drilling, abrasion arthroplasty, microfracture) may provide some benefit in smaller and/or less symptomatic lesions, they tend to be less effective and less durable in larger and/or more symptomatic lesions (McPherson and Tubo, 2000).

**FIG. 80.3.** There is a wide range of clinical presentations of articular-cartilage injury in the knee. Treatment options reflect severity, based on a combination of patient, lesion, and comorbidity factors. The clinical experience with ACI has been at the more severe end of the spectrum of full-thickness articular-cartilage injury.

## II. CLINICAL EXPERIENCE WITH FIRST-GENERATION ACI

### Initial Experience

Lars Peterson and colleagues, in Gothenburg, Sweden, pioneered the clinical application of autologous cultured chondrocytes to repair symptomatic articular-cartilage lesions in the knee joint. The initial results in 23 patients with a mean follow-up of 39 months were published in a landmark paper in 1994 (Brittberg *et al.*, 1994). Results were reported for clinical outcome scores, macroscopic appearance during second look investigational arthroscopies, and histology evaluation of repair tissue biopsies (Fig. 80.4). Clinical results were good to excellent in 14 of 16 lesions (87.5%) on the femoral condyles. Eleven of 15 biopsies (73%) on the femoral condyles had the appearance of hyaline cartilage. Initial results in the seven patella lesions were less promising. Later experience with patella implants, in which patella alignment was addressed concurrently with cell implantation, yielded better results (Peterson *et al.*, 2000; Minas and Bryant, 2005).

### Cell Processing and Surgical Technique

The basic techniques and promising results reported in this initial study became the basis for a larger long-term experience at Peterson's center as well as the commercialization and multicenter experience with ACI. In 1995, Genzyme Corporation established (and subsequently obtained an FDA license for) a commercial GMP facility in the United States to perform the isolation and expansion of chondrocytes from cartilage biopsies. Also in 1995, a multicenter registry was established to track outcomes of ACI and other cartilage procedures. In 1997, the FDA approved Carticel® (autologous cultured chondrocytes) as

**FIG. 80.4.** Histologic section from a biopsy of cartilage repair tissue 36 months after treatment with autologous chondrocyte implantation of an articular-cartilage defect on the femoral condyle. From Brittberg *et al.* (1994). Copyright © 1994 Massachusetts Medical Society. All rights reserved.

the first cell therapy in orthopedics. Over 12,000 patients have now been treated with Carticel®. Other commercial cell-culturing facilities have been established outside the United States.

ACI is a two-stage procedure. In the first stage, a 200 to 300-mg specimen of cartilage is harvested arthroscopically from a lesser weight-bearing area of the trochlea ridge or the intercondylar notch. In the United States, the procedure is to send this sample to the Genzyme facility (Cambridge, MA), where the sample is enzymatically digested and the chondrocytes are isolated, expanded through primary and secondary culture, and then cryopreserved. Once the facility has been notified of an implantation date by the surgeon

**FIG. 80.5.** Flow diagram for Carticel® (autologous cultured chondrocytes) patient lot-specific cartilage biopsy harvest, cGMP cell processing, and surgical implantation. Copyright © 2002 Genzyme Corporation. All rights reserved.

and the hospital, the cryopreserved cells are thawed and cultured to expand the cell population *in vitro*. The final product, a suspension of approximately 12 million cells, is shipped for implantation in a second-stage surgery (Fig. 80.5). All implants are tested for appropriate chondrocytic morphology, sterility, endotoxin, and cell viability as part of the release specifications. The extensive process validation and sterility-testing procedures for this unique, patient lot-specific manufacturing process have been described in detail elsewhere (McPherson and Tubo, 2000; Kielpinski *et al.*, 2005).

The cells are implanted via an arthrotomy, in which an autologous periosteal flap is harvested from the proximal tibia or distal femur, and sutured over the defect and the cells are injected into the defect under the patch after testing for a watertight seal. Fibrin glue can be used if needed to ensure a watertight seal (Fig. 80.6.)

### Long-Term Outcomes in the Swedish Series

Peterson *et al.* (2000) reported outcomes for 94 patients implanted between 1987 and 1995, with only one patient lost to follow-up. The patients were divided into five treatment groups based on defect classification and concurrent ACL procedures. Baseline characteristics and mean follow-up varied by defect category. In general these patients had large, chronic lesions and multiple prior surgeries. The mean defect size ranged from a 4.2 cm<sup>2</sup> in isolated femoral lesions to 4.7 cm<sup>2</sup> in OCD lesions. Mean follow-up ranged from 2.7 years in the multiple-lesion group to 4.2 years (range 2–9 years) in the isolated femoral condyle group. Outcome results based on patient assessment varied by defect category, with isolated femoral condyles 92% improved, femoral condyles with ACL reconstruction 75%

improved, OCD lesions 89% improved, multiple lesions 67% improved, and patella defects 68% improved.

Peterson *et al.* (2002) assessed durability of ACI in 61 patients with a mean follow-up of 7.4 years (range 5–11). Durability was assessed by comparing two-year follow-up results with longer-term follow-up. In addition to clinical outcome scores, 11 patients were assessed with second look arthroscopy, indentation probe, and biopsy. The key finding of this study is the durability of results from two years to longer follow-up, at a mean of 7.4 years. At two years, 50 of 61 patients (82%) had results graded as good or excellent; at 5–11 years' follow-up, 51 of 61 patients (84%) had results graded as good or excellent. Eight of 12 biopsies (67%) were graded as hyaline, and four of 12 (33%) were graded as fibrous. There were 10 treatment failures overall (16%), with the rate varying by defect treatment group. The lowest failure rate was in the isolated femoral condyle group (11%) and highest in the patella group (24%). Seven of the 10 treatment failures occurred in the first two years post-ACI, and the three other failures were rated fair to poor at two years. No patient rated as good or excellent at two years failed between two and 11 years.

### Multicenter Registry Studies

Micheli *et al.* (2001) reported results for the first 50 Cartilage Repair Registry patients with a minimum of three years of follow-up. The mean lesion size was 4.2 cm<sup>2</sup>, and the median baseline modified Cincinnati score was 3. Thirty-nine patients (78%) had undergone one or more articular-cartilage procedures in the five years prior to ACI, and 13 patients (26%) had undergone three or more such procedures.

**FIG. 80.6.** Surgical implantation of first-generation ACI. The figure illustrates (1) harvest of periosteal patch, (2) suturing of periosteal patch over cartilage defect on femoral condyle, and (3) catheter in place for injection of autologous cultured chondrocytes under sutured patch. After chondrocyte injection, the catheter is removed and the catheter entry site is sealed with additional suture. Copyright © 2006 Genzyme Corporation. All rights reserved.

This study reported both patient and clinician evaluations. There was a close correlation between patient-reported scores and clinician evaluations. Improvement was seen in 85% of patients, 2% were unchanged, and 13% declined. Patients reported a median improvement of 5 points on the overall 10-point modified Cincinnati score from a median baseline of “3” (“poor” — “significant limitations affect activities of daily living”) to a median score of “8” (“very good” — “only a few limitations with sports”) at three-year follow-up. Eleven patients, including three treatment failures, underwent subsequent operations. The most common cause of symptoms requiring further intervention was hypertrophy of the periosteal patch, which occurred in six patients.

Browne *et al.* (2005) reported results for the first 100 Cartilage Repair Registry patients with femoral lesions to reach the five-year follow-up time frame. The majority of patients (70%) had at least one cartilage repair procedure

prior to the index arthroscopy. Eighty-five percent had a single defect with a mean size of 4.2 cm<sup>2</sup>, and 15% of patients had multiple defects with a mean lesion size of 9 cm<sup>2</sup>.

The mean baseline score was 3.2. Eighty-seven patients completed full follow-up. Overall, mean Cincinnati scores improved by 2.6 points ( $p < .0001$ ). Of the 87 patients who completed follow-up, 62 (71%) improved, 6 (7%) reported no change, and 19 (22%) worsened. Of the 62 who improved, the overall Cincinnati score improved 4.1 points from baseline ( $p < 0.0001$ ). The authors concluded that “Patients in this study represent a clinical challenge with few treatment options. Despite the large lesions, prior surgical history, and poor function of patients at baseline, 71% of patients reported improvement in their overall condition score five years after implantation.”

Fu *et al.* (2005) directly compared two Cartilage Registry Repair cohorts at three-year follow-up: a cohort of 58 debridement patients and a cohort of 58 ACI patients. The two cohorts had similar demographics and defect pathologies at baseline. However, more ACI patients failed a previous debridement or marrow stimulation procedure than the debridement patients. The mean total defect area for the debridement cohort was 4.5 cm<sup>2</sup>, and for the ACI cohort it was 5 cm<sup>2</sup>.

Fifty-six ACI patients and 42 debridement patients completed follow-up outcome assessments. Eighty-one percent of the ACI patients and 60% of the debridement patients reported median improvements of 5 and 2 points, respectively, in the overall condition score. ACI patients also reported greater improvements in the median pain and swelling scores than debridement patients. The treatment failure rate was the same for both ACI and debridement patients. Based on the *a priori* definition of treatment failure, there were three (5.2%) failures in the debridement group and four (6.9%) in the ACI group. The authors concluded that “Although patients treated with debridement for symptomatic, large, focal, chondral defects of the distal femur had some functional improvement at follow-up, ACI patients obtained higher levels of knee function and had greater relief from pain and swelling at three years.”

Micheli *et al.* (2006) reported on ACI outcomes in children and adolescents. Thirty-seven registry patients with a mean lesion size of 5.2 cm<sup>2</sup> and a mean age of 16 at implant were in the cohort. Despite the young age of these patients, they were similar to adult ACI cohorts, in that the majority (70%) had undergone at least one prior knee procedure before the index arthroscopy for cartilage specimen harvest. Thirty-two patients completed follow-up assessments at a mean follow-up of 4.3 years. Twenty-eight patients (88%) reported a favorable outcome at a minimum of two-year follow-up.

### Other Studies of ACI

Knutsen *et al.* (2004) in Norway conducted a four-center, 80-patient randomized controlled trial comparing ACI to

microfracture at a two-year follow-up. Endpoints were clinical outcome scores (Lysholm, VAS pain score, and SF-36) and a histology score. Both groups were improved at two years, with no statistically significant difference between the ACI and microfracture groups in Lysholm, VAS pain score, or SF-36 mental health subscale (results reported in aggregate, i.e., not stratified by lesion size). The authors do report a statistically significant difference in the SF-36 physical component score in favor of the microfracture arm; however, the authors also report different SF-36 physical component mean scores at baseline between the arms.

The authors report that microfracture outcomes varied by lesion size:

In the microfracture group, patients with a lesion smaller than 4 cm<sup>2</sup> had significantly better clinical results (according to the Lysholm score, VAS pain score, and SF-36 physical component score) than those with a bigger defect ( $p < 0.003$ ). We did not find this association between the size of the defect and the clinical outcome in the autologous chondrocyte implantation group ( $p > 0.89$ ).

With regard to the histology comparison, the authors conclude, “There was a tendency in our study for the autologous chondrocyte implantation procedure to result in more hyaline repair cartilage than the microfracture procedure, but this was not a significant finding with the numbers available.”

Study strengths include that it is a prospective, randomized trial. Limitations include that there were no trochlea lesions in the study, and the patient baseline condition appears to be less severe than the U.S. Carticel patient population. The authors concluded that “because microfracture is a relatively simple one-stage procedure, it may be more suitable for a primary first-line cartilage repair of a local contained defect. In patients in whom microfracture has failed and in those with bigger, noncontained defects, autologous chondrocyte implantation may be a better option.”

Bentley *et al.* (2003) in the United Kingdom conducted a single-center, 100-patient randomized controlled trial comparing two ACI arms (ACI with periosteal flap coverage and ACI with type I/III collagen membrane coverage) to mosaicplasty, with a mean follow-up of 1.7 years. Outcome measures include clinical scores, second look arthroscopy with ICRS scoring, and histology.

The results overall favor ACI as compared to mosaicplasty in all measured parameters, including clinical outcome scores, histology results, and ICRS scoring on follow-up arthroscopy. Overall, 88% of the ACI patients vs. 69% of the mosaicplasty patients were graded as “excellent or good result.”

Study strengths include that it is a prospective, randomized design with follow-up arthroscopy evaluation as well as clinical outcome scores. In addition, the patients in this study do appear to have some comparability to U.S. Carticel patients in terms of mean lesion size, baseline symptoms,

and prior surgical history. Mean lesion size is 4.66 cm<sup>2</sup>. Mean duration of symptoms was 7.2 years, and all but six patients had undergone previous surgical interventions. Limitations of the study include that while the study showed better scores for ACI vs. mosaicplasty in all parameters, the differences in clinical scores were statistically significant for only one anatomic location, the medial femoral condyle.

The authors conclude, “There is definite evidence, however, that ACI is valuable for selected patients in that it gives healing of hyaline cartilage in chondral and osteochondral defects. It can also dramatically reduce the symptoms of pain and disability. The continued use of mosaicplasty, however, appears to be dubious.”

There are several other published studies on ACI from other centers. They are too numerous to review in detail here. In general, the results are similar to the studies just discussed. A few specific additional points are worth noting with regard to special populations or indications treated with ACI and health economics of this technology. Mithofer *et al.* (2005) reported on ACI to treat adolescent athletes. Overall, they report a 96% rate of return to high-impact sports and 60% achieving an athletic level equal to or higher than the preinjury level. Return rate to preinjury sports rate correlated with shorter preoperative symptom duration and a lower number of prior operations. This suggests that earlier intervention may optimize cell-therapy outcomes, an especially important consideration in younger patients.

Minas has reported successful outcomes in young adults with complex joint pathology for which ACI was performed as an alternative to an artificial joint arthroplasty (Minas, 2001; Minas and Bryant, 2005). Further, while the vast majority of ACI cases are in the knee, there are limited reports of successful use in other joints, especially the ankle. While the patient lot-specific manufacture of a live cellular product with stringent quality controls is inherently expensive, favorable health economics were demonstrated in three studies that assessed economic parameters (Minas, 1998; Lindahl *et al.*, 2001; Yates, 2003).

### Complications of ACI

Patients who undergo ACI may require subsequent surgical procedures on the treated knee. The majority of these procedures are arthroscopic interventions. Such procedures frequently have no findings attributable to ACI. The most common findings assessed related to ACI is graft overgrowth or tissue hypertrophy. This complication can present with symptoms of “catching” or “clicking” and generally responds well to arthroscopic debridement. The next-most-common findings at arthroscopy assessed as related to ACI treatment are joint adhesions or arthrofibrosis. These are treated with manipulation under anesthesia or arthroscopic lysis of adhesions. Graft complications, such as partial delamination of the graft and periosteal patch, have also been reported as findings at subsequent surgical procedures.

Multiple prior surgeries and a history of ligament reconstruction or meniscal procedures concomitant with ACI appear to be risk factors for a post-ACI subsequent procedure. The frequency of arthroscopic intervention after ACI is likely due to a combination of factors, including the associated arthrotomy necessary for implantation, complex knee pathology, including comorbid conditions, concurrent procedures and prior surgical history, and a hypertrophy of the graft or periosteal patch some patients.

### Summary of First-Generation ACI Clinical Experience

The data sources just summarized all have strengths and limitations, and no single source is definitive. Multiple factors make direct comparisons or data synthesis of these varied studies challenging. These factors include differences in study design, data collection instruments, length of follow-up, evaluation criteria, treatment failure definitions, and patient populations. However, bearing these factors in mind, these different studies are generally consistent and complementary in supporting the following overall conclusions regarding the efficacy of first-generation ACI:

- ACI has demonstrated successful clinical outcomes in challenging large, symptomatic cartilage lesions where other treatment modalities, such as debridement, microfracture, and osteochondral autografts, have been less successful.
- ACI has demonstrated successful clinical outcomes in patients who have failed prior cartilage repair procedures.
- ACI has demonstrated the ability to improve patients with very severe disability at baseline, such as pain and dysfunction with activities of daily living.

While these are important advances, first-generation ACI has limitations. These include the harvest and suturing of a periosteal flap to secure the implanted chondrocytes in the defect. Not only does this prolong the operative time and require a more extensive arthrotomy, but some authors have postulated that the periosteal flap may contribute to the formation of hypertrophic tissue, the most common complication of first-generation ACI (Bentley *et al.*, 2003; Willers *et al.*, 2005). These limitations have led to efforts to develop improved technology for chondrocyte implantation. Goals include maintaining the benefits of achieving biological cartilage resurfacing and functional repair tissue while improving surgical delivery and reducing complications.

### III. CLINICAL EXPERIENCE WITH SECOND-GENERATION ACI

A significant degree of early clinical experience with second-generation ACI has been obtained in Europe and Australia. The first clinical step was to replace the autologous periosteal flap with a porcine type I/III collagen patch.

**FIG. 80.7.** Second-generation autologous cultured chondrocyte graft technology. In matrix-induced autologous chondrocyte implantation (MACI®), the cultured chondrocytes are seeded on 4 × 5-cm type I/III collagen membrane. This eliminates the need for the periosteal patch and extensive suturing used in first-generation ACI and facilitates less invasive surgical implantation. Copyright© 2005 Genzyme Corporation. All rights reserved.

This has been termed CACI, or collagen-covered ACI. Early results suggested clinical and histological results similar to periosteum-covered ACI, but with a lower incidence of post-implant hypertrophy (Briggs *et al.*, 2003; Bentley *et al.*, 2003).

In CACI, the chondrocytes are still delivered to the defect in a liquid suspension that requires suturing a collagen patch in place with a watertight seal. A further innovation was to combine the chondrocytes with an implantable membrane at the end stages of the culturing process. The chondrocytes adhere to the membrane and can be implanted as a construct that eliminates extensive suturing and facilitates less invasive surgical approaches (Fig. 80.7). Two different types of membrane are used in this manner and marketed outside the United States as second-generation ACI products. In matrix-induced autologous chondrocyte implantation (MACI®) (Genzyme Biosurgery, Cambridge, MA) the chondrocytes are seeded on a 4 × 5-cm porcine type I/III collagen membrane. In Hyalograft C® (FAB, Abano, Italy) chondrocytes are seeded on a 2 × 2-cm Hyaff 11 membrane, an esterified derivative of hyaluronan. Other biomaterial approaches to delivering chondrocytes for cartilage repair are being pursued by several entities, but they do not have extensive clinical experience to date.

Over 4000 patients have been implanted with second-generation ACI. The early clinical experience is promising, in that it meets the goals for a second-generation ACI technology (Bartlett *et al.*, 2005; Ronga *et al.*, 2005; Marlovits *et al.*, 2004, 2006; Marcacci *et al.*, 2005; D'Anchise *et al.*, 2005).

This approach eliminates the periosteal patch and can be implanted less invasively with sutureless fixation. The next step for clinical development of second-generation ACI will be further controlled clinical trials that meet the requirements for product registration (BLA) in the United States and other jurisdictions that are developing similar regulations for cell-based therapies.

#### IV. CONCLUSIONS

Further progress in treating articular-cartilage lesions is likely to come from several approaches, including the incremental improvement of autologous cultured chondrocyte implantation. Given the range of clinical presentations as outlined in the chapter introduction, it is unlikely that a single technology will be applicable to the entire spectrum of articular-cartilage pathology. Instead, one can envision an array of diagnostic and therapeutic tools to enable orthopedists to treat effectively each stage of cartilage injury and comorbid injury. These could include further development of cell-based therapy as well as other approaches, such as biomaterial implants alone or combined with repair-stimulating growth factors, which may be more applicable to different stage diseases.

There is a continuum from early chondral injury, identified when it may still be relatively asymptomatic, to symptomatic focal cartilage injury to end-stage arthritis. At the early end of this continuum is a need to better identify and mitigate the risk of progression of disease. Second-generation ACI focuses on improved delivery of autologous cultured chondrocytes for treatment of symptomatic cartilage lesions. This is well along in clinical development. Additional work is needed to assess the applicability of

cell-therapy approaches to arthritis. This may include synthetic osteochondral constructs and is likely to focus on indications where traditional arthroplasty has the most limitations, e.g., younger, athletic patients. Synthetic osteochondral constructs may also be applicable for other etiologies, such as OCD lesions with extensive bone deficiency.

The clinical applications of cell-therapy tissue engineering to date have focused on autologous cultured chondrocytes. As discussed elsewhere in this book, there is extensive preclinical work on a wide range of other cell sources, such as adipose cells, mesenchymal and embryonic stem cells, and allogeneic chondrocytes, that have the potential to expand the clinical applications to other cell types. Cell modification strategies using gene therapy or growth factors to mediate cartilage repair with different cell types are also under preclinical investigation and have the potential to broaden the scope of cell-therapy clinical applications.

Developing and producing surgical implants with live cells poses scientific, logistical, commercial, and clinical challenges that are very different from the challenges with the development and production of more traditional orthopedic implants. To the extent that future cell-therapy applications in cartilage repair require *in vitro* cell processing on a manufacturing scale, the experience with Carticel® (autologous cultured chondrocytes) demonstrates the feasibility of manufacturing a high-quality cell product for surgical implantation. The clinical success with first-generation ACI in a patient population with very symptomatic and challenging cartilage lesions has laid the foundation for further progress in cell-based orthopedic-tissue engineering in general and cartilage repair in particular.

### I. INTRODUCTION

This chapter addresses the history and evolution of the three major constituents of bone that make up the necessary elements for current and future tissue-engineered bone replacements and adjuncts to bone repair. Today's clinical usage of various biomaterials has evolved from advances in the understanding and development of these three elements: those that are osteogenic, osteoconductive, and osteoinductive. One particular focus addresses the osteoinductive element, for it is within this class of materials that the increases in understanding, development, and manufacture have been the greatest. The reason the market for contemporary bone grafting has grown and why there has been measurable progress toward the goal of minimizing or eliminating autogenous iliac crest graft harvesting is due to the products' mimicking the osteoinductive element. The clinical use of composite grafting as a method to accomplish tissue engineering today is growing, and the developments of the last decade or so have set the stage for even more effective bone graft substances and the surgical techniques to use them effectively.

For centuries, one goal of medical specialists has been the creation of a viable substitute to repair bone. Through

the ages, substances such as ivory, leather, noble metals, plaster of Paris, directly transplanted hard tissues from other species, and other hard substances have been used in an attempt to heal or repair bone tissues; all attempts were met with either short-term failures, long-term failures, or non-reproducible results. These earliest attempts were essentially empirical, for it was thought bone was a hard, lifeless structure that merely served to keep the body erect. They did, however, document the interest of individuals who dealt with addressing maladies of the body in repair and/or replacing damaged parts. Using the best knowledge and insight at hand at the time, the body tissues were attempted to be engineered. In the most recent decades, and armed with the perfect vision of hindsight, researchers and clinicians have made more noble attempts to develop substances to aid in the repair and regeneration of bone. The evolution of more discriminating analytical techniques and progress in materials science have allowed a more educated, targeted approach toward the quest, and advances in surgical technique and instrumentation have made attempts more successful. Just as with many other compounds and structures, engineering various constituents to perform together in a specific fashion now dominates product development of

most biomaterials, including body tissues such as bone. Effectively no different than electrical or civil engineering, *tissue engineering* has become a common term in everyday biomaterials and hard-tissue clinical practice.

That bone was composed of several constituents capable of being separated and analyzed was realized in the early 1950s (Carlstrom and Engstrom, 1956; Eanes and Posner, 1970; Eastoe and Eastoe, 1954; Eastoe, 1956; Glimscher, 1959). Bone, now well studied, is known to be a complex, vital, and necessary composite tissue in the body, containing many individual constituents, and the analysis of bone has provided the basis for trying to mimic each piece and the whole (Recker, 2002). Over time, developmental efforts have attempted to subdivide the elements of bone and to mimic them on a sequentially smaller and smaller scale. With this methodology, the number of elements and the complexity of the duplication had increased (Davies, 2000). To engineer bone properly in today's world, one would have to split the material apart, create the best analogs to each constituent, and then recombine them in a manner that provides function in an orthopedic procedure. This will, no doubt, change, with the future offering replacement bones and bone segments "grown" *in situ*.

Finally, the advances in load-bearing medical device procedures, such as total hip replacement, total knee replacement, internal and external fracture fixation, and spinal instrumentation, have given rise to a need to develop and expand bone graft technology. For example, the use of structural allograft spacers and metallic spinal fusion cages has fostered the development of many bone graft substances to fill the spaces in their interiors, to aid bone adaptation at and in their surfaces, and to support the components designed to support patient loading.

## II. BONE HEALING

Without an understanding of the bone-healing process, development of bone repair materials and tissue augmentation would not be possible. The bone regeneration and repair process is not completely understood, but greater secrets have been unlocked on a seemingly monthly basis, and with this ever-increasing knowledge, more effective materials have been engineered. Traditionally, bone healing has been separated into four stages of healing: inflammation and clot formation, cellular infiltration and soft-callus formation, hard-callus formation, and remodeling. In terms of the actions that initiate the mechanism of repair leading to successful healing, the first stage is the most important, because both a favorable biological environment and mechanical stability need to be established to maximize the opportunity for a successful clinical outcome. In the following sections, various classes of materials are discussed. These advances in the elements of tissue engineering are designed to aid the normal bone-healing sequence, not make up for shortcomings in establishing the environment or stability for healing; in that way, they can increase the

chances for a successful outcome. No bone-grafting material is designed to overcome factors that may impede bone healing, such as smoking, alcohol, NSAIDS, an immunocompromised host, soft-tissue disruption, and infection. While very complex from a biochemistry standpoint, the ability to regenerate bone and the most effective tissue-engineered bone grafts used today employ three basic elements of bone repair: osteogenic materials, osteoconductive materials, and osteoinductive materials (Helm, 2001; Kalfas, 2001; Pilitsas, 2002; Urist, 1965). The body employs all three to a greater or lesser degree, depending on the site of regeneration or repair and/or the severity of the repair problem. The three have also been summarized as cells, scaffolds, and signals. In contemporary bone-grafting language, the use of two or more such elements is called *composite bone grafting*.

## III. OSTEOGENIC GRAFTING MATERIALS

Osteogenic substances are ideally suited to perform as constituents of a bone graft because they have cellular constituents like those present at the host site. They are transplanted from one place in the body to another and may be transplanted directly, but they may also be treated in one way or another in between harvesting and implantation. The key feature of any osteogenic component is the presence of vital cells and a spectrum of naturally occurring proteins that can differentiate pluripotent stem cells down osteoblastic pathways (Cheng *et al.*, 2003).

Autograft bone, considered the gold standard, is the ideal bone graft if its vitality is maintained and it is securely affixed within the implant bed. The transplanted cells within an autograft are provided with a biologically familiar environment in which to perform as they would prior to transplantation, without any immunogenic response triggered by the host (Muschler *et al.*, 2003). The life span of these vital cells, however, is not known once removed from the body, nor is the optimal storage medium to preserve vitality for the time between harvest and use (Betz, 2002).

Bulk autogenous grafts can sustain functional loads if they are securely affixed and incorporated; morselized or minced-up autogenous bone has the advantage of containing vital cells and being formable and mixable with other graft materials to provide an osteogenic element to an osteoconductive and/or osteoinductive substance (Fleming, 2000). Division of the bone into small pieces has the advantage of providing a greater surface area and access to the vital cellular elements. For general bone-void filling of defects and posterolateral spinal fusions, minced, finely divided autogenous bone provides maximum release of osteogenic elements through high surface area; the trade-offs of fine mincing are most likely shorter vitality time, longer preparation time, and a greater need for containment. The pain, morbidity, and disadvantages of harvesting iliac crest autograft are well established, including long-term pain and the inability to serve as a future harvest site.

**FIG. 81.1.** Reducing autograft into smaller pieces is an effective way to provide greater access of vital cellular elements, because the surface area is increased. Depending on the application, mincing by rongeurs and creating even smaller pieces in a bone mill are effective ways to add osteogenic elements into a bone graft.

And the advantages are documented as well: Notwithstanding its gold standard status, it is associated with an estimated 15–25% nonunion rate. One report estimates that approximately one-third of the harvest patients experience long-term (over two years) pain and complications (Burkus *et al.*, 2002b) (Fig. 81.1). Nonetheless, autograft is routinely used in orthopedic surgical procedures and it serves as the control for most preclinical and clinical evaluations, either required or strongly recommended by such regulatory agencies as the U.S. Food and Drug Administration (FDA) or for corporate marketing purposes; it has the most extensive historical database and is accepted as an appropriate positive control for performance comparisons.

A less invasive source of vital osteogenic cells is through the harvesting of bone marrow aspirate from the iliac crest or other marrow cavities. Such harvesting has become popular in recent years as the concept of composite grafting, the intentional combining of the essential elements previously described, grew in popularity and the desire to minimize or preclude iliac crest autograft harvests became a greater focus. Harvesting of bone-marrow aspirate is very technique sensitive, in that diligence must be exercised in order to yield a high volume of aspirate while minimizing excessive blood draw, and it is controversial in its reports of efficacy (Muschler, 2003; Hernigou, 2005; Fleming, 2000; Lieberman, 2006; Muschler, 2006). A relatively simple, inexpensive, disposable needle-type device (Fig. 81.2) can be used for bone-marrow aspirate harvesting. The osteogenic nature of the aspirate is acknowledged, but it may be that concentration is the only way to provide an efficacious, vital composite graft constituent (Hernigou, 2005). Bone marrow aspirated from the iliac crest, for example, is often substantially diluted by peripheral blood; studies indicate that

**FIG. 81.2.** A device for obtaining bone marrow aspirate employs a less invasive approach to marrow-rich sources such as the iliac crest, without the second-site surgery, pain, and/or longer-term morbidities and complications of larger autograft harvests.

maintenance of a higher concentration of the osteogenic cells can be achieved by limiting the aspiration volume to 1–2 mL (Fleming, 2000). In concentrating the aspirate, one must be careful to protect the cells from mechanical damage, which would decrease the vitality of the aspirate. Nevertheless, bone-marrow aspirate can provide an osteogenic cell-containing addition to a composite graft that helps to create a moldable, packable graft or a surface coating on a porous implant such as a structural allograft.

The motivation to avoid harvesting bone from the iliac crest, along with the advent of composite grafting, has fostered the use of a series of blood-derived or “blood spin-down” products to enhance graft performance further. The concept is founded on the recognition that certain portions of the blood contain growth regulatory factors that may stimulate bone formation. Referred to as *platelet-rich plasma* (PRP) and/or autologous growth factors (AGF®), and on occasion improperly represented as similar to bone-marrow aspirate, these are a source of endogenous growth factors that are believed to act directly on reparative cells. Originally developed as an adjunct for wound healing, PRP contains a mixture of growth factors, primarily cytokines, that were later believed to enhance healing of osseous tissue, especially when combined with autograft. The reports in the literature are mixed, though mostly negative, regarding the efficacy of these materials when used as a stand-alone bone graft material (Anitua, 1999; Froum, 2002; Marx, 1998). However, these blood-derived products are effective in containing the multiple components used in composite grafts. Typically, a modestly priced, disposable blood-contact harvesting and container system is provided for single-patient use, with the centrifuge unit a fixed, nonfluid contact piece of operating room equipment.

The presence of osteogenic material containing vital cells is an important requirement for any bone graft. A properly prepared implant bed, such as complete decortication in the posteriolateral gutters of the spine, debridement of the segments of an osseous nonunion, and reaming to bleeding bone in the acetabulum, provides an osteogenic-element source and a viable site for the initiation of new bone formation; any additional vital cells within a bone graft add to the potential for successful bone formation. Used properly, osteogenic material can aid in hastening healing as part of a composite graft; its absence will not necessarily preclude healing but will reduce the chance for a successful outcome, especially in compromised sites and demanding applications.

#### IV. OSTEOCONDUCTIVE BONE GRAFT MATERIALS

A critical part of natural bone during normal healing is its function as a scaffold for the newly apposing bone to grow on. Without that function as an osteoconductive substrate, differentiated cells would have no place to attach and build to effect the repair. Over 80 years ago, it was recognized that bone contained a mineral constituent composed primarily of a calcium phosphate (CaP) apatitic structure and that biological apatite exists as minute crystals on and within the bone collagen fibrils (deJong, 1926; Carlstrom and Engstrom, 1956; Eanes and Posner, 1970). In an effort to create a synthetic analog to bone mineral and in recognition that biocompatibility is a necessary element for any bone substrate, researchers created calcium phosphate-containing materials that were shown to exhibit the desired scaffolding characteristics. Hydroxylapatite (HA) and tricalcium phosphate (TCP) ceramics as well as calcium phosphate-based glasses were extensively characterized and found their way into clinical use in dental, oral and maxillofacial, and small-bone-void-filling applications (Laurencin, 2003). Their function as biocompatible substrates was further demonstrated by their extensive use as coatings for metallic dental and orthopedic prostheses, where they served as substrates for bone growth and adaptation (Geesink and Manley, 1993). Porous forms of ceramic HA and/or TCP have survived the rather empirical approach to substrate development and are the most utilized physical forms for bone-void filling; the porous structure provides a favorable microenvironment for cellular attachment. The CaPs have the additional advantages of relatively small production costs, no risk of disease transmission, and unlimited supply. Years of clinical use have demonstrated that they are purely conductive substrates, and care should be taken that they not be relied on as the sole graft material in larger defects. Another limitation of the CaPs stems from their brittle ceramic nature, so they are not greatly load bearing in block form and cannot be conveniently be cut and shaped by the clinician without risk of fracture. The

FDA has classified most synthetic biomaterials as class II devices, requiring 510(k) submission and approval before commercialization; other regulatory agencies around the world, for the most part, classify the CaPs the same.

The most clinically utilized osteoconductive substrate is a natural one, allograft bone. Allograft bone, tissue transplanted from one human to another, has been processed in many ways over the years. Allograft can be fresh frozen or alternatively processed to minimize the potential of immunogenic response that may be elicited when used for filling a bone defect, acting as a void filler and scaffold for conducting new bone proliferation. Allograft can be cortical or cancellous bone. Structural allografts have enjoyed widespread use as a weight-bearing spacer for anterior spinal fusions. They are made by milling or precision-cutting the bone to create functional shapes in much the same function as metal or polymer materials are fabricated into space-preserving configurations. Cancellous bone, while not structural or capable of bearing significant loads, has become the most widely used form of bone-void filler and scaffold for new bone formation (Fig. 81.3). Cancellous bone chips are processed from cadaveric bone by tissue banks into various shapes and sizes. The greatest advantages of allograft are its availability, incorporation by bone, the ability to be fused with natural bone, and the modulus of elasticity. Processed allograft tissues with no additives are currently considered tissue for transplantation by the FDA and other regulatory bodies.

Over the last 30 years, interconnecting biocompatible porous metal coatings have been used to promote the fixation of hard-tissue implants through bone ingrowth (Bobyne *et al.*, 1980; Cook *et al.*, 1985). The success of biological ingrowth into a surface of a porous metal is based on the biocompatibility of the specific metal, titanium, cobalt-chrome alloy, and tantalum, for example. Since the mid-1990s, certain porous metals, most notably titanium and tantalum, have been shown to provide the function of an osteoconductive scaffold by mimicking in metal the interconnecting nature and mechanical properties of trabecular bone. They provide structural support, can be shaped and fixated with screws like bone, and thereby provide strength and ductility with a favorable environment for bone adaptation and ingrowth without the potential long-term liability of collapse or preferential resorption (Fig. 81.4) (Bobyne *et al.*, 1999, 2004).

Over the last ten years or so, the use of allograft bone has grown as processing techniques have become more sophisticated, the safety of such grafts has become less an issue, and the limitations of metallic load-bearing structures (modulus of elasticity, nonresorbable nature, etc.) become more important. Organizations such as the American Association of Tissue Banks (AATB) have helped in establishing guidelines for processed tissue, with the FDA and other regulatory bodies using such guidelines as part of the basis for approval for marketing and widespread clinical use.

**FIG. 81.3.** (A) Cancellous chips are the most common form of allograft material used, due to their price, availability, biocompatibility, and track record as an osteoconductive bone graft extender. (B) Synthetic calcium phosphate ceramics based on tricalcium phosphate (TCP), hydroxylapatite (HA), or combinations (HA/TCP) are bone graft extenders that provide a biocompatible chemistry, favorable microenvironment, and porosity for bone adaptation. ## V. OSTEOINDUCTIVE BONE GRAFT MATERIALS

Dr. Marshall Urist was the first to publish in a peer-reviewed journal a paper identifying the osteoinductive potential of demineralized bone matrix (DBM) (Urist, 1965). The first clinical use of a DBM-like substance goes back much further, when demineralized bovine xenograft was used successfully to repair long-bone and cranial defects in dogs and tibial defects in humans (Senn, 1889). Bone repairs itself by a complex series of steps and reactions that are mitigated by a series of naturally occurring proteins and growth factors that orchestrate the cellular recruitment, differentiation, and proliferation in the bone regeneration and repair process. The exact sequence and process the body uses are, at this writing, not entirely known. The DBM process is designed essentially to concentrate and make

**FIG. 81.4.** Porous tantalum structure with high (75–80%) porosity and ~430- $\mu$ m interconnected pore size used as a substitute for structural allograft and as an implant ingrowth surface. Zimmer, Inc. — Trabecular Metal®.

more readily available the elements responsible for participation in the natural sequence while removing those constituents that may get in the way of it.

Today, DBM is made from human bone by removing the natural mineral of ground cortical bone, leaving the bone collagen and native bone morphogenic proteins access to the bone repair environment. In making DBM, soft-tissue and cellular elements are removed through physical stripping, cutting, and a series of alcohol and washing treatments, and cancellous bone is removed. The diaphyseal region of the long bones provide the greatest yield and are the donor bones sought for DBM production; the cortical bone is ground to between 125 and 850 microns. Several demineralization processes can be used, but typically hydrochloric acid is used to leach out the mineral constituent. Other washing and cleansing steps render a material of granular, powdery consistency comprising primarily bone collagen and several noncollagenous proteins, notably the bone morphogenic proteins. It took roughly 15 years for the concept of DBM to start to be used clinically, but containment of the small particles in a bone void was difficult, even with the use of blood or other material. In the early 1990s, the realization that DBM efficacy could be improved through the use of a containing carrier revolutionized the concept of osteoinductivity. The first carrier used to deliver DBM particles was glycerol, a water-soluble and biocompatible substance that, when combined with DBM, has a flowable consistency that allows delivery to the surgical site through an open-bore syringe. Subsequently, other inactive (noninductive) carriers were developed and used to deliver the active DBM particles, thus establishing a new and growing material concept in the clinical bone repair and augmentation industry (Fig. 81.5). The procurement of donor tissues and the processing of

**FIG. 81.5.** A flowable putty form of inductive DBM particles contained in an inert (noninductive) carrier to facilitate convenient delivery and maintenance of the particles in the surgical site and to provide containment when the bone graft is extended with autograft, local bone, and/or osteoconductor. Isotis OrthoBiologics, Inc.

DBM is an established industry, with standards, controls, and demonstrations of efficacy in preclinical studies in support of regulatory applications. There are many suitable carriers used in commercially available DBM-based bone graft materials: sodium hyaluronate, glycerol, calcium sulfate and carboxymethylcellulose, lecithin, reverse-phase poloxamer, and porcine collagen. All are inert, in that they are not demonstrated to be capable of fostering cell differentiation down osteoblastic pathways as determined by validated *in vitro* or *in vivo* methods. The American Association of Tissue Banks (AATB, 2006) has established a series of guidelines for the preparation and quality maintenance of transplanted human tissues, and the FDA and other regulatory bodies around the world have, or are creating, governmental guidelines or requirements for the manufacture and use of these inductive substances (FDA, 2006). The advantages of such combinations are containment of the inductive particles in the surgical site and surgeon-friendly delivery. Such nonactive carriers must be removed to reveal the active BMPs and GFs to the bone repair environment, and they represent a limitation in use, since the inductivity of the combination is limited in part by the percentage of particles and the ability of the body to metabolize the carrier quickly. A balance must exist between carrier technology and biological function: If the carrier is metabolized too quickly, the active DBM particles may not be contained within the site long enough to aid in the differentiation and repair process, while if too slow or if locked in a mass of slowly resorbing material, the active DBM may not have access to the bone repair milieu in the optimal time to aid in the early stages of bone repair.

Until November 15, 2005, the DBM/carrier substances were commercialized with no prerequisite FDA approval to

market; on that date, the combination of active DBM particles and any inactive carrier or ingredient were categorized as medical devices requiring application and FDA approval to market, before commercialization. The acceptance of the concepts of osteoinductivity by the clinical community fostered the development of other-than-putty and gel formulations to matrix, sponge, or fleece forms. The three-dimensional matrices are not generally bone derived, with dermal or tendon collagen used most frequently. The advantages of DBM-based materials are their long-term clinical use, their relatively low cost, and their graft-containment characteristics; they can form the basis of a composite graft of inductive, conductive, and osteogenic elements and have found increasing use in the bone repair arena. The disadvantages are the donor-based variability of DBM, the lower volume of inductive elements for some substances, the lack of any standardized measurement technique for DBM inductivity, and the inert carriers.

A recent innovation in the development and use of osteoinductive biomaterials came with the recognition of the limitations of an inert carrier for DBM particles, a further treatment of DBM particles to expose more effectively the naturally inductive elements found in bone. These natural human BMP-containing materials, nhBMP™, use the natural bone constituents themselves to form a flowable, inductive carrier for active DBM particles, thus providing a putty form of inductive graft material that does not suffer the liability of an inert carrier that must be removed before exposure of inductive particles becomes available to the bone repair site. The providing of greater inductivity within such materials is supported by the quantitation of various BMPs and GFs using contemporary analytical techniques (Kay *et al.*, 2005). The bone response is faster and more robust based on the carrier entering into the differentiation cascade and more effectively triggering the bone repair cascade. A spectrum of naturally occurring BMPs and growth factors is preserved in both the carrier and particles and is responsible for a more concentrated delivery of differentiating agents to the surgical site. Both flowable putty and lyophilized matrix forms are available for clinical use and have no inert ingredient additives (Fig. 81.6). The matrix form provides a spectrum of BMPs and GFs in a highly porous structure that allows for immediate mobilization and delivery of an inductive stimulus to the site, a distinct advantage over first-generation DBM-inert carrier combinations. The advantages of this class of substances are their moderate cost, high osteoinductivity, and lack of an inert carrier, while the disadvantage is the DBM-based nature, including the potential donor-based variability.

Genetic engineering has provided yet another source of osteoinductive bone graft materials. Since the mid-1980s, researchers have sought to identify the single BMP that can best trigger and accelerate bone healing. The individual BMPs from DBM were isolated and genetically engineered to increase yields that allowed implantation and assessment

**FIG. 81.6.** (A) A matrix form of inductive bone graft material composed of inductive DBM particles contained in an inductive DBM-derived carrier. This material is made by lyophilizing a flowable DBM particle/DBM-based carrier substance to remove the moisture, resulting in the open, porous structure. (B) Scanning electron micrograph showing matrix and included DBM particles. (C) The use of an inductive matrix form to hold vital bone-marrow aspirate, as a composite graft. IsoTis OrthoBiologics, Inc. SEM magnification 50 $\times$ , scale 1 mm.

of individual capability to induce bone formation. Two recombinant BMPs, BMP-2 and BMP-7, are commercially available for several specific FDA-approved indications. These rhBMPs evolved from early studies on DBM and the specific BMPs contained therein. BMP-7 and BMP-2 were among those identified and were chosen by two commercial entities for development (Wozney, 2002; Rengachary, 2003; Sandberg, 1993). Preclinical studies showed acceleration of bone healing in a variety of defects, leading to the human clinical evaluations in application-specific studies (Boden *et al.*, 1996; Lovell, 1989; Schimandle, 1995). The recombinant BMPs provided for reduced blood loss, shorter operating times, and elimination of iliac crest harvesting but nonstatistically different fusion rates, assessed clinically and radiographically, over autograft. One recombinant form combined with autograft had no clinical advantage over autograft (Vaccaro, 2003).

Today, each commercially available recombinant material is provided in highly concentrated form, with a small quantity of an inert, osteoconductive carrier substance, dosed specifically for certain clinically approved indications, and each has been shown to be safe and effective. This class of inductive biomaterial appears to be most effective when on-label indications are followed, based on establishment of dosage, delivery, and efficacy (Burkus *et al.*, 2002a, 2002b). The clinical indications will increase based on additional ongoing clinical evaluations to determine dosage, delivery, and efficacy.

The advantages of the rhBMPs are their demonstrated ability to elicit a significant osseous response in the approved indications and the extensive clinical studies available to document the usage, while the disadvantages are the high cost, limited reimbursement, and potential side effects, associated primarily with off-label use, which can be serious in nature (Pradhan *et al.*, 2006; Smucker *et al.*, 2006; Treharne, 2004). Much more in-depth information on the recombinant materials can be obtained in other chapters of this book.

Perhaps more than the other two elements, advances in the development of osteoinductive agents and their demonstrated ability to influence the pathway of cellular differentiation have become the basis for contemporary concepts in tissue engineering. Advances in the understanding of bone induction and the introduction of substances designed specifically to address this mechanism are signs that treatment of bone healing is being pursued from a more advanced, mechanistic approach, representing truly relevant progress in our understanding. In the desire to use osteoinduction to aid in bone healing, the surgeon has had an expanded selection of materials to choose from since the turn of the century with the advent of higher-potency rhBMP and nhBMP<sup>TM</sup> technologies.

With the changes in the FDA posture to classify such osteoinductive materials as devices, the burden of proof has risen. There are no peer-reviewed publications that describe

well-conducted comparisons between any two osteoinductive materials. There are two primary reasons for this. First, the industry is relatively young and such studies are expensive, and to be published today, they would have to have been initiated some five to six years ago; this would have been too costly at that time. Second, because the substances were considered tissues for transplantation, there was no regulatory need. Today and going forward, specific orthopedic applications will necessarily be supported by clinical studies.

Osteoinductivity has been demonstrated in several *in vivo* and *in vitro* assays whose heritage goes back to the early work of Urist. He implanted test substances into the soft tissue of athymic rodents, and, if osteoinductive, they differentiated cells down osteoblastic pathways and resulted in bone-nodule formation; similar differentiation has been observed in a laboratory culture model and validated against the classic athymic rodent model (Urist, 1965; Urist and Strates, 1971; Katagiri *et al.*, 1994; Han *et al.*, 2003; Honsawek *et al.*, 2005).

The advantage of the osteoinductive materials as a class is the providing of nonautogenous triggering agents for cell differentiation down osteoblastic lines, thus aiding the initiation of the bone repair process. Dosage, concentration, delivery, and carrier substance appear to be the major determinants of clinical utility, while cost and regulatory status have effects on usage in certain clinical applications and institutions. Demineralized bone matrix particles contained in noninductive carriers, DBM particles in inductive DBM-based carriers, and recombinant biomaterials technologies are the currently available subdivisions within the class of osteoinductors, each delivering some level of inductive constituent to aid in the bone repair process.

## VI. COMPOSITE BONE GRAFTING

Composite bone grafting has become a preferred grafting philosophy and is the treatment modality of choice for many surgeons. The concept employs a selected combination of osteoconductive, osteoinductive, and osteogenic materials a clinician believes will achieve the best clinical result for that patient. As noted previously, the body employs all three mechanisms to some degree, depending on the site of regeneration or repair and/or the severity of the repair situation. Many options for cells, scaffolds, and signals are available to the clinician from each category, and the selection should be based on what clinical result is desired and the data to support each constituent's use, cost, and personal surgical techniques. Each constituent need not necessarily be harvested or obtained specifically for use as a graft material in every procedure; for example, a completely decorticated posteriorlateral spine or reamed acetabulum will often provide enough bleeding vital bone to preclude any additional autologous material, even bone-marrow aspirate (Fig. 81.7). The surgeon is faced with a continuum of different bone defects, each with a different intrinsic

**FIG. 81.7.** A composite graft to preclude iliac crest harvest employing minced local bone to provide the osteogenic component, synthetic TCP to supply the conductive component, and a DBM-based putty form to provide osteoinduction, handling, and containment. Modest amounts of the synthetic are used, and the relative proportions are chosen to facilitate containment during and after placement.

ability to aid in bone healing. The options are there to use. While there is no universally accepted formula, several are provided in the clinical examples that follow in a later section. There are many sources of information about bone graft materials and their use; among them is one distributed and updated regularly by the American Academy of Orthopaedic Surgeons (AAOS) (AAOS, 2006).

## VII. REGULATORY ISSUES

The FDA regulates and provides the approval for use of medical devices and drugs after the demonstration of safety and efficacy. Many regulatory agencies of countries outside the United States utilize similar, if not identical, requirements and criteria for controlling and regulating bone graft

materials. Currently, the materials described in this summary are all considered either medical devices or tissues for transplantation, requiring various degrees of approval, or none, at this writing. Cancellous bone chips and DBM-based materials with no inert ingredients added are considered tissues for transplantation and are presently governed by 21 CFR1270. Other substances are medical devices requiring either approval to market via the 510(k) process (21CFR-807, Subsection E), or the premarket approval (PMA) process pursuant to 21CFR-812 and 21CFR-814. The package insert for each material is important because it contains instructions for use, approved indications, contraindications, warnings, and other information important to understand before selecting the substances for clinical use in patients. The warnings and contraindications are particularly important because they are generally derived from specifically identified instances, complications, or test results. Specifically approved indications for the product are termed *on-label* uses, whereas all others are termed *off-label*. Additional information may be obtained from manufacturers' websites and product descriptions, in addition to promotional literature, published journal articles, clinical forums, and the like. In selecting constituents for composite bone grafting, the surgeon should consider the status of the biological and mechanical environments for bone healing and patient comorbidities and issues and then choose the most efficacious combination of the three essential elements to be used in consideration of the indications, contraindications, warnings, and prior clinical experience available.

## VIII. EXAMPLES OF TISSUE ENGINEERING IN CONTEMPORARY CLINICAL ORTHOPEDICS

Bone graft materials are used in a variety of clinical orthopedic procedures, including spinal fusion, total joint replacement, trauma, nonunions, oral and craniofacial, and other void- and defect-filling applications. The 2005 market for grafting and graft materials in the United States was estimated at approximately \$1.8 billion and worldwide at almost \$2.3 billion, with growth at an approximate 13.5% per year (Knowledge Enterprises, 2006). Worldwide, over 2.5 million procedures account for the substantial and growing market. The predominant use of graft materials is in the spine. This is a particularly demanding and often high-volume use of bone graft materials, where bone is used to fuse the unstable or damaged spinal vertebrae. The use of graft materials in the spine requires growth of bone to perform a function where it does not occur naturally. Almost all other grafting procedures involve the regeneration of bone where it would normally occur; such is the case in trauma, total joint arthroplasty, and other orthopedic applications of bone graft materials.

The growing market opportunity is the driving force for investment in tissue engineering and the development of

better and more efficacious grafting materials and techniques. The ultimate reason for the increase in bone grafting is more consistent, predictable clinical results. This trend is occurring. Aside from the new materials, the ability to create composite grafts from several different constituents is an advance in clinical practice. The clinical community has become more sophisticated as well, with clinical professionals sometimes aiding in the discovery and development of new materials, concepts, and clinical applications.

The uses of bone graft materials have expanded greatly since the mid-1990s, and to provide individual, specific examples of that evolution is beyond the scope of this chapter. Figures 81.8 and 81.9 present two individual cases, however, where state-of-the-art bone-grafting techniques involving contemporary, cost-effective, and accepted concepts of tissue engineering have been used to treat several common orthopedic conditions.

## IX. THE FUTURE

The future of bone-tissue engineering is bright. Engineers and scientists are constantly unlocking the secrets to the process of bone formation and healing. Biochemists and materials scientists are understanding and copying nature's codes, regulators, and biological substances more effectively, so the combinations of building blocks, triggers, and controls that will be tested and mass produced are greater and more effective. Advances in the development of each of the three elements of bone regeneration are taking place. Better osteoconductive scaffolds with greater affinity for new bone and more predictable bioresorption profiles are under development. The combinations of biopolymers, bioceramics, and naturally derived (collagen, for example) materials better mimics the existing natural scaffolds of bone in callus, vital autograft, and cancellous bone. More potent and/or optimally dosed natural, synthetic, or genetically engineered bone inductors are being evaluated for site-specific applicability and in combination with other carriers. Autogenous materials are being looked at for vitality preservation, *ex vivo* expansion, and optimization of potential with minimization of harvest insult. With the advances in osteoinductive biomaterials and the demonstration of the efficacy of composite grafting, it is doubtful that autograft use will increase. Future technologies, such as stem cell therapy and autogenous organ (bone) regeneration, are within the realm of possibility.

Several approaches in tissue engineering are being taken, so it is unclear whether in the future substances will be placed in a site, perhaps bear load, and become quickly incorporated and bioresorbed to leave a natural architecture and chemistry, or whether a fast-acting substance will be placed in a bone repair site to "supertrigger" the mobilization of natural body elements that heal the site using a body-derived series of materials in a natural sequence but at a highly rate-accelerated process. Both pathways can be envisioned, and both are being pursued within the

**FIG. 81.8.** Clavicle nonunion treated with a combination of a high-inductivity putty and inductive matrix form after thorough debridement and application of internal fixation. Gaps are filled with the putty, and the matrix is form cut and placed adjacent to the plate, with final contouring with the putty form. IsoTis OrthoBiologics, Inc.

academic and institutional research environments. Each pathway has its advantages and developmental challenges, but the work being done and the materials and processes being used and tested today increase the knowledge base and the art going forward. Clearly, orthopedic surgeons and their patients will benefit from the advances in biomaterials tissue engineering and the demonstration of their efficacy.

## X. CONCLUSIONS

Bone is a complex tissue. An engineered bone replacement has been a noble challenge, but advances are being made. The next edition of this volume will undoubtedly discuss further advances. This chapter has focused on the materials used in contemporary tissue-engineered bone grafts. These more potent and efficacious new materials, however, do not reduce the need for application of sound orthopedic principles of bone healing or understanding the

effects of the comorbidities that can have negative effects on bone healing. The establishment of an ideal environment for hard-tissue healing and mechanical stability is essential. Three elements are required for bone repair: osteogenic cells, an osteoconductive growth substrate, and a substance that aids in cell differentiation. Many alternatives are available to the orthopedic surgeon today. It is the surgeon's educated judgment as to the most appropriate treatment for an individual patient, so a thorough understanding of the bone-healing process, the indications, contraindications, warnings, and handling characteristics of all materials at their disposal is most important in bone healing. This information is found on the device package insert and on the Internet, among other places. Finally, access to these new technologies will be limited or slowed by regulatory processes in place to ensure safe and effective products for clinical use.

### I. INTRODUCTION

Cardiovascular disease is by far the most common reason for morbidity and mortality in the Western world. It comprises malfunction of heart valves, blood vessels, and myocardium, all of which are subject to tissue-engineering programs. The development of tissue-engineered heart valves is fueled by the idea to create a growing valve for children with congenital cardiac malformations and a totally autologous biological valve for adults with acquired valve defects. Here the tissue-engineered product has to compare favorably to the existing spectrum of quite sophisticated and long-term approved biological and mechanical prostheses. Blood vessel engineering aims predominantly at generating small-diameter (<6 mm; e.g., coronary arteries) rather than large-diameter vessels (e.g., aorta, large mesenteric or femoral arteries). Dacron and other polymers are being used in the latter, with satisfying results. The driving forces in this field are the low long-term patency rates of classical saphenous vein grafts and the paucity of suitable arterial vessels (such as the internal mammary artery) in coronary bypass surgery. Other potential applications include arteriovenous shunts for patients on chronic

hemodialysis. Finally, myocardial-tissue engineering aims at creating force-developing cardiac tissue patches to correct cardiac congenital malformations in children ("the growing patch") and replace or support heart muscle function after myocardial infarction or in patients with cardiomyopathies. The total bioartificial heart, as publicly announced in the mid-1990s, would comprise all of the three tissue-engineering fields and would be the straight alternative to heart transplantation. But even with some very encouraging progress in many facets of the field, the total bioartificial heart remains a dream rather than a reasonable clinical perspective in the next 20 years.

If one searches Medline for "tissue engineering" and limits the search to clinical trials, only 26 papers pop up, none of them dealing with cardiovascular products. Instead, skin, cartilage, bone, and some urological applications have been tested in patients. This reflects, on the one hand, the differing advancements of various tissue-engineering fields, but it certainly also points at a problem: Testing skin is technically simple and bears only a limited risk to the patient, even in case of complete failure. Failure of a heart valve, a coronary artery conduit, or a load-carrying heart muscle

patch, in contrast, would have disastrous consequences, as sadly proven in a study with decellularized porcine heart valves produced by CryoLife and implanted in children in Austria (Simon *et al.*, 2003). From the reported data, the valve had been implanted in children, and several died or had to be reoperated on. This disaster did not completely stop the development of decellularized xenogeneic valves, but it clearly raised the bar for further clinical trials in this field.

This chapter gives an overview on the current development of the three major tissue-engineered cardiovascular products (valves, vessels, and myocardium) but focuses mainly on myocardial-tissue patch engineering, being the field the authors have been actively involved in. For more thorough reviews on valves and vessels, the reader is referred to excellent recent papers (Isenberg *et al.*, 2006; Vesely, 2005).

## II. CLINICAL NEED FOR TISSUE-ENGINEERED CARDIOVASCULAR PRODUCTS?

Cardiovascular medicine has been among the most successful fields since the mid-1980s, and the progress made via improved drug therapy, invasive cardiology, cardiac surgery, and cardiac devices is impressive. Yet mortality and morbidity remain high, and it is unquestionable that there is room for improvement.

### Heart Valves

Malfunctioning heart valves are generally replaced surgically by either mechanical or biological prostheses, a procedure performed in more than 100,000 patients per year in the United States and more than 300,000 worldwide (Vesely, 2005). Whereas valve replacement is often life-saving and has a tremendous impact on quality of life, drawbacks do exist. Mechanical prostheses require life-long anticoagulation, with its potential hazards, and are still associated with a markedly increased rate of thromboembolism (4% per year) (Hammermeister *et al.*, 1993). Biological prostheses do not share these problems, but they have a limited half-life. None of the existing models grows, with the consequence that children with congenital valvular malformation have to be reoperated on with age. The ideal tissue-engineered living valves would overcome all of these problems. Yet the strength of these arguments has to be critically weighed. In particular, the best biological prostheses, such as the aortic homografts and the Edwards pericardial valve, have a durability close to 20 years (Biglioli *et al.*, 2004). In fact, this will often be lifelong, given that the majority of patients undergoing valve replacement are over 50 years old. Moreover, surgical techniques have improved and the high mortality associated with repeated valve replacements (formerly approximately 20%) has gone down considerably to approximately 4% (Vesely, 2005), allowing the option of repeated use of bioprosthetic valves rather than implanting a mechan-

ical valve. Thus, progress through tissue engineering appears most likely to be relevant in children with congenital malformations, where the availability of growing valves would constitute a major advancement.

### Blood Vessels

Considering that the market for heart valves is large, it becomes clearly evident, by looking at the patient numbers, that the need for blood vessels is even larger. Every year, 500,000 procedures are being performed that involve small-caliber blood vessels just in the United States (Isenberg *et al.*, 2006). For many years, poly(ethylene terephthalate) (PET; Dacron) or poly(tetrafluorethylene) (PTFE; Teflon) grafts have been in clinical use for the replacement or repair of large-diameter blood vessels, such as the aorta and the carotid arteries, with good results (Naylor *et al.*, 2004; Post *et al.*, 2001). In contrast, replacement of small-diameter vessels, such as coronary arteries, still requires venous or arterial autografts. The standard saphenous vein graft as used in coronary artery bypass grafting (CABG) has a high risk of acute or chronic vessel occlusion and requires a second surgical procedure. This does not apply to arterial autografts, such as the internal mammary artery, but this graft is often not available in sufficient number or quality. Thus, there is a clear need for tissue-engineered small arteries.

### Myocardial Patches

Compared to current treatment options (drugs, devices, transplantation, prostheses, cell therapy), cardiac repair with tissue-engineered myocardial patches appears complicated, expensive, and still very ambitious. Yet there are at least two areas where tissue engineering could prove to be valuable. The first, and maybe the most obvious, is reconstructing malformed hearts in children; the other, quantitatively much more important, is repairing infarcted or failing hearts in adults.

Heart malformations that might benefit from restoration using biological, autologous muscle patches include several forms of ventricular dysplasia, such as the hypoplastic left heart syndrome or tricuspid atresia with right ventricular dysplasia. Right now most of these infants undergo palliative surgery (a univentricular correction) ("Fontan-surgery"). Biologic active muscle patches might allow biventricular correction and true ventricular restoration. In addition, indications for a right ventricular outflow tract patch plasty are quite frequent in patients with pulmonary atresia or "Fallot"-type malformations, who might also benefit from a biological solution.

In contrast to cardiac malformations, myocardial infarction and its consequences belong to the most common diseases with huge socioeconomic impact. For the reason discussed earlier, namely the availability of conservative therapeutic options, only a minor fraction of patients surviving an acute myocardial infarction will be candidates for

biological cardiac repair. Present cell-based clinical studies employ bone marrow-derived cells in patients with relatively well-preserved left ventricular (LV) function after acute myocardial infarction (Assmus *et al.*, 2002; Janssens *et al.*, 2006; Stamm *et al.*, 2003; Strauer *et al.*, 2002; Wollert *et al.*, 2004). These patients are very common and easy to study, but several arguments indicate that they are not the best-suited population for tissue-engineering strategies. First, if LV function is only mildly affected, the effect of an intervention aiming at providing the heart with new contractile myocardium is necessarily small. Second, current treatment after myocardial infarction with beta-blockers, statins, aspirin, and potentially ACE inhibitors is simple, safe, and quite effective, with a well-documented reduction of morbidity and mortality (Hippisley-Cox and Coupland, 2005). Third, spontaneous recovery, e.g., by improved perfusion and structural adaptation of the heart, namely by hypertrophy, occurs and obscures the potential effect of tissue patches. Finally, implanting tissue patches requires open heart surgery, which will not be justified in mild forms of cardiac disease. More likely, implantation of tissue patches could be considered in patients with chronic heart failure resulting from myocardial infarction. These patients might in fact benefit from a combination of tissue-engineered patch grafting, ventricular restoration surgery ("Dor-plasty"), surgical revascularization, and valve repair (Vitali *et al.*, 2003). A combination of the Dor-plasty and subsequent implantation of a contractile patch seems especially promising and would ideally enable complete functional regeneration of the ventricle (Eschenhagen and Zimmermann, 2005).

Whereas it is hardly disputable that numerous patients would profit from a direct support of contractile function, the question is whether tissue-engineered patches could play a significant role in this scenario when compared to current alternatives: (1) Mechanical left ventricular-assist devices (LVADs) acutely support the pumping activity of the left ventricle and thereby allow the heart to recover, a process leading to "reverse remodeling" (Wohlschlaeger *et al.*, 2005). Yet it seems unlikely that LVADs can completely and stably reverse a severe cardiac disease. Therefore, the place of LV-assist devices is bridging to transplantation rather than in long-term therapy. (2) Implantable defibrillators/cardioverters protect against lethal arrhythmias and thereby prolong survival (Bardy *et al.*, 2005) but in themselves have no effect on contractile function and heart failure symptoms. (3) Cardiac resynchronization therapy by means of biventricular pacing, in contrast, leads to improved heart function and has a documented effect on survival (Cleland *et al.*, 2005). Yet only a limited number of patients (those with conduction abnormalities) profit from this new therapy. (4) The ACORN device (Starling and Jessup, 2004) may be valuable in a limited subset of patients with large ventricles, but it is also hampered by severe complications, e.g., constrictive cardiomyopathy-like symptoms. Finally it seems clear that heart transplantation remains the only curative

therapy for terminal heart failure. However, the number of candidates largely exceeds the number of suitable donor organs, and this ratio has not improved over the years (Cai and Terasaki, 2004).

When considering a tissue-engineering strategy for patients with terminal heart failure, two different scenarios can be envisioned. The simple one is to add patches of tissue-engineered heart muscle on the diseased heart. A more elaborate one is to excise nonfunctioning myocardium and replace it with an engineered heart muscle patch. Obviously, the latter approach requires high mechanical stability of the patch to withstand systolic pressure, and this may be quite difficult to achieve. Thus, adding tissue-engineered patches to the heart ("biological ACORN") rather than replacing diseased parts is the more realistic perspective at this point.

### III. REQUIREMENTS FOR CLINICAL APPLICATION

The specific requirements for heart valves and blood vessels differ substantially from those for myocardial patches and are discussed only briefly here. The main part of this section focuses on the requirements for a clinical introduction of myocardial patches. The function of a heart valve depends mainly on its extracellular matrix component. In fact, the biological heart valves used today contain no living cell (e.g., the glutaraldehyd-fixed porcine xenograft or the bovine pericardial valve) or lose all their cellular components over time, as observed in case of the homografts (Schoen *et al.*, 1995). Thus, the currently used heart prostheses are essentially passivated structures in the bloodstream (Vesely, 2005). The hope of heart valve-tissue engineering is that, in the end, endothelialization of the prostheses reduces the risk of thromboembolism and immune responses and improves longevity, though this assumption remains unproven yet. In contrast, small-diameter blood vessels and heart muscle patches clearly depend on their cellular constituent to maintain function and longevity. Blood vessels need not only a high tensile strength as measured by the burst strength and an elastic component to provide recoil but also an intact endothelial cell layer to prevent thrombosis and to regulate vascular tone (Isenberg *et al.*, 2006). Myocardial patches need to generate systolic force, exhibit diastolic compliance, and, in case they were intended to withstand systolic blood pressure, high tensile strength. Given these features it becomes evident that the cellular component in myocardial patches plays a more prominent role than its matrix components. Finally, an important difference between the requirement for blood vessels and heart valves on the one hand and myocardial patches on the other is that the former can be engineered at a sufficient size without their own vascularization. In the following subsections, the conceptional requirements for a tissue-engineered myocardial patch are discussed in detail.

### A Tissue-Engineered Heart Muscle Patch Should Be Composed of Heart Cells

Engineered heart muscle should consist of bona fide myocardial tissue, including cardiac myocytes, blood vessels, and other cells that make up normal heart tissue. Whereas this criterion may appear trivial, it is not undisputed, and evidence exists that implantation of tissue-engineered constructs with nonmyocytes (Miyahara *et al.*, 2006) or without cells (Kofidis *et al.*, 2004) can have favorable effects on heart function, at least in animal models. Moreover, cardiac reconstructions with Dacron patches or other nonbiological materials is already a clinical reality. Thus, the necessity to create naturelike patches of heart muscles in the culture dish, with all the problems discussed herein, can well be challenged. Arguments for it are, at this point, partly derived experimentally, partly theoretical. Important experimental evidence comes from the failure of the “skeletal myoplasty approach” in heart failure. It was based on the observation that chronic electrical stimulation of skeletal muscle induces the expression of slow, cardiac-like myosin isoforms, which led to the hope that skeletal myocytes have the capacity to transdifferentiate into cardiac myocytes or at least into electrically coupling cardiac myocytelike cells. One early skeletal myoplasty procedure was the *latissimus dorsi plastic*, in which a vascularized piece of this muscle was surgically wrapped around the heart and electrically stimulated (Carpentier and Chachques, 1985). The other skeletal muscle-based procedure was the injection of autologous skeletal myoblasts (Menasche *et al.*, 2001). Neither the first nor the second approach turned out to be suitable to generate new myocardium in failing hearts. In fact, the first large randomized, placebo-controlled study with skeletal myoblasts was prematurely terminated in early 2006 due to a lack of efficacy and safety (personal communication). Though difficult to deduce from clinical studies, it is very likely that the absence of cardiac differentiation and the paucity of electrical coupling between the implanted skeletal myocytes and the host cardiac myocytes (Reinecke *et al.*, 2002) can induce life-threatening reentry tachyarrhythmias (Abraham *et al.*, 2005).

### A Tissue-Engineered Heart Muscle Patch Should Contain a Natural Extracellular Matrix

It is quite clear that the ideal engineered heart muscle should resemble natural heart tissue and therefore contain also natural extracellular matrix materials such as collagen type I/III and other basal membrane constituents. The question in the field is, rather, how to approach this aim. One strategy is to use the decellularized biomatrix of a heart and repopulate it with cardiac myocytes and the other cells that constitute heart muscle. Here the challenge is to employ chemical decellularization procedures that do not alter the matrix and do not interfere with the reseeding process. The second strategy is to let the cells produce their own matrix

and just keep them in a three-dimensional space of the desired form for a given time until they have produced their own matrix. The third one is to design synthetic polymers that mimic the natural matrix as faithfully as possible and seed cells onto it. This ideal scaffold for cardiac-tissue engineering should promote cardiac-tissue formation, should be moldable in any desired three-dimensional form, and be biodegradable, nonimmunogenic, and nontoxic. They must, on the one hand, be highly compliant not to decrease diastolic properties and, on the other hand, exhibit mechanical strength to allow manual handling and systolic loading, especially if applied in the left ventricle.

### The Patch Should Have a Myocardiumlike Structure

Immature cells from embryonic chick and neonatal rat hearts exhibit a striking degree of remodeling capacity and, under suitable conditions, such as gyratory shaking, form beating, three-dimensional heartlike tissues, as already shown in the early 1950s (Moscona and Moscona, 1952). Similarly, embryonic stem cells easily form three-dimensional embryoid bodies that frequently contain beating cardiomyocytes (Martin and Evans, 1975). Histologically and functionally, these structures resemble immature cardiac tissues. Yet the usefulness of these structures for cardiac repair appears limited, for the following reasons: (1) They are relatively small (a few 10–100  $\mu\text{m}$ ); (2) they are spheric and do not exhibit the propensity to fuse spontaneously to larger, beating aggregates; (3) they contain randomly oriented rather than aligned cardiomyocytes. Thus, twitch force development of such aggregates is small and necessarily undirected, making simple cell aggregates unlikely to be suited for cardiac repair strategies. The three-dimensional structure and the muscle strand orientation of the ideal patch, in contrast, should be guided toward a physiological muscle architecture. In general, a longitudinal, parallel orientation of cardiac muscle strands will be desirable, because this is a major requisite for directed force development. Yet the normal heart has a complex macroarchitecture with differently oriented muscle layers to support a wringing motion, to squeeze the blood forcefully into the circulation, rather than a straight contraction (Davis *et al.*, 2001). These biophysical aspects need to be taken into consideration when muscle patches are to be applied to replace complex myocardial structures *in vivo*.

### The Patch Should Develop Relevant Contractile Force

Maximal forces of intact cardiac preparations are in the range of 50  $\text{mN}/\text{mm}^2$  (Hasenfuss *et al.*, 1991). The force an engineered tissue patch develops can be taken as a good indicator of the cardiac tissue quality. It depends on several factors, including the fraction of the tissue occupied by cardiac myocytes (approximately 80% in normal cardiac tissue), the fraction of cardiac myocytes occupied by sarco-

meres (normally 45%), the maturation of the sarcomeres (normally a semicrystalline, highly organized structure), and the isoforms of myofilament proteins (expression of adult rather than fetal isoforms; e.g., fast  $\alpha$ -myosin heavy chain rather than the slow  $\beta$ -myosin heavy chain in rodents) as well as the orientation of muscle strands in parallel.

### **The Patch Needs a Minimal Critical Size**

The patch needs to be manufactured at a size large enough to affect realistically the function of an entire left ventricle or to be useful for cardiac reconstruction in case of malformations in childhood. It has been estimated that the human heart, which weighs around 300 g, contains 5 billion myocytes (Beltrami *et al.*, 1994). If an infarction was critical when >30% of the left ventricular mass was affected and one assumes the weight of the left ventricle to be half of that of a total heart including the atria then an ideal therapy would have to replace approximately 750 million cardiac myocytes. Such a patch would have a weight of 45 g or a size, for example, of  $7 \times 7 \times 0.92$  cm.

### **The Patch Should Be Vascularized**

Present tissue-engineering experiences as well as studies of embryonic development, comparative anatomical studies in different species, and the biology of tumor formation show that a critical size of a tissue cannot be surpassed without perfusion of nutrients and oxygen, generally by vascularization. For example, in the absence of capillarization and perfusion, tumors implanted into nude mice did not reach a diameter of more than 2–3 mm (Folkman, 1971). These values, however, depend on both the metabolic demand and the cellular density of the respective tissue. Beating cardiac myocytes obviously have a very high metabolic activity. Accordingly, the density of capillaries in the adult heart is very high, amounting to approximately 2400–3300/mm<sup>2</sup> in rat and human at different postnatal stages (intercapillary distance ~19–20  $\mu$ m) (Korecky *et al.*, 1982; Rakusan *et al.*, 1992). On the other hand, the early embryonic rat heart (until embryonic day 16) as well as the adult frog heart are avascular and nourished exclusively from the lumen by blood circulating within the trabecular system (Ratajska *et al.*, 2003; Sys *et al.*, 1997). Thus, large heart muscles develop either through vascularization or through intense trabecularization, with a single trabecel diameter being smaller than 50–75  $\mu$ m. Given that an implanted patch has to survive in a nonperfused environment (the surface of the heart), sufficiently large patches for the human heart are likely to be possible only when the patch contains a functioning vasculature that can be surgically connected to the host circulation.

### **The Patch Should Be Electrically Stable and Not Induce Arrhythmias**

Sudden cardiac death, most commonly resulting from fatal arrhythmia, accounts for approximately 50% of

cardiac death (one-third of total deaths). The two major arrhythmogenic mechanisms are reentry due to conduction abnormalities and abnormal automaticity, often as the consequence of cardiac repolarization defects (“heart failure is an acquired LQT syndrome”). Thus, the potential proarrhythmic risks of any tissue-engineering approach in heart failure has to be rigorously evaluated. The ideal patch should have no pacemaker potential that might act as a focus of automaticity. Even more importantly, the ideal patch should integrate robustly into the electrical syncytium of the host myocardium, on the one hand to be excited by the naturally propagated sinus rhythm and develop synchronized force and on the other hand not to cause arrhythmia. Suboptimal coupling could be even worse than no coupling because delayed conduction inevitably favors reentry circuits.

### **The Patch Should Be Autologous**

Organ transplantation represents major progress in modern medicine and justifies the need for life-long immunosuppression, with its unavoidable side effects. At first glance, it appears unrealistic to assume that patients and physicians would accept life-long immunosuppression to maintain a tissue-engineered patch. Therefore, the search for an autologous cell source and the design of totally autologous culture conditions is a major aim in the field. However, if cardiac-tissue engineering was to offer a curative treatment to patients who lack the alternative of conservative treatment or classical heart transplantation, then immunosuppression, with its side effects, appears acceptable.

### **Tissue-Engineered Heart Muscle Must Be Generated Under GMP and GLP Guidelines**

If a tissue-engineering strategy is to enter the clinical arena one day, it has to be developed under good manufacturing and good laboratory practice procedures (GMP and GLP). This means, for example, that xenogeneic compounds such as animal sera in the culture media have to be avoided, sterility must be ensured, and reproducibility is granted. This may actually make first-generation tissue-engineering products exceedingly expensive. Yet this is unlikely to be the real limiting factor for its further exploration because improvements in manufacturing processes, including large-scale production, are likely to reduce overall costs.

## **IV. CURRENT CONCEPTS AND ACHIEVEMENTS IN ENGINEERING CARDIOVASCULAR PRODUCTS**

The principal strategies in tissue engineering of valves, vessels, and myocardium are quite similar and have been developed in parallel, partly independent from each other. They can be broadly categorized into four approaches: (1) cell seeding onto decellularized native tissues, (2) cell seeding onto biodegradable polymer scaffolds, (3) cell

entrapment in naturally occurring biogels such as collagen I and fibrin, and (4) the cell sheet technique. Consistent evidence exists that tissue formation can be significantly improved by chronic mechanical loading and culture under nonstatic conditions in a bioreactor.

### Decellularized Tissue

One of two strategies that actually made the way to clinical application so far is the unfixed, decellularized porcine valve, both with and without subsequent cell seeding. Decellularization of native tissues is the simplest technique and, in fact, does not require any specific tissue-engineering or cell biology procedure. Conceptionally, the natural tissue provides the ideal three-dimensional form, and decellularization is expected to reduce immune reactions inherent in the cellular component of the valve. However, the process of decellularization, usually performed with hyper- or hypotonic solutions, mild detergents, and proteolytic enzymes, exerts detrimental effects on the matrix that can give rise to thromboembolic complications and mechanical instability of the graft. Indeed, shortly after the first children received the acellular CryoLife valve in Vienna, Austria, serious valvular complications occurred and at least three children died (Simon *et al.*, 2003). The exact number of patients that received these grafts has never been reported. Despite these disastrous results, decellularized unseeded porcine valves, obtained via a different procedure, are still being implanted. A series of 50 patients in Berlin received such a graft during a Ross operation (replacement of the defective aortic valve by the endogenous pulmonary artery valve and implantation of the porcine valve in the pulmonary, low-pressure position), with apparently good results (Dohmen *et al.*, 2006; Konertz *et al.*, 2005). However, there is unpublished evidence that a number of patients has indeed died from valve-related complications (Vesely, 2005), casting serious doubts on this approach. The alternative approach that actually applies principles of tissue engineering is to repopulate the decellularized porcine valve with autologous, patient-derived cells *in vitro*. The expectation is that this procedure restores the biology of the graft, reduces thromboembolic complications, immune responses, and mechanical deterioration over time, and ultimately allows the valve to grow with the recipient. Indeed, positive results have been reported from experiments in sheep (Lichtenberg *et al.*, 2006) as well as from first implantations in children in the pulmonary position (A. Haverich, conference talk in Bad Reichenhall, Germany, February 2006). However, it appears too early to decide whether or not this approach can compare or even be superior to existing prostheses, such as the homograft of glutaraldehyde-fixed porcine or bovine pericardial valves.

Decellularized blood vessels and vessel-like structures made from small intestine submucosa (SIS) have also been tested, but overall the success appears limited (reviewed in Isenberg *et al.*, 2006). Similar to the valves, the process of

decellularization apparently has detrimental effects on the tissue, leading to reduced tensile strength and compliance and shrinkage. Consequently, the decellularized blood vessels undergo aneurysm formation, infection, and thrombosis (Teebken and Haverich, 2002).

Similar to valves and vessels, there has been discussion about decellularizing whole hearts and repopulating the matrix with heart cells. Despite the apparent appeal of the idea, such a total bioartificial heart appears a rather unlikely option for therapy, given that one would have to reconstitute not only the heart muscle, but also the valves and the vessels, and this on the scale of a human heart. Thus, one could think of heart muscle patches derived from decellularized heart pieces, potentially with a perfusing vessel. Such experiments are ongoing in different laboratories but have not been published.

### Biodegradable Polymer Scaffolds

The second approach is to seed the respective cardiovascular cell type onto porous, biodegradable polymer scaffolds. Conceptionally the polymer serves as a three-dimensional template for the desired organ, and the cells are expected to degrade the polymer and produce their own extracellular matrix. This conventional tissue-engineering approach has the great advantage that the scaffold can theoretically be manufactured at any desired size, form, or microstructure and with various chemical and biological properties. In practice, however, the success in the cardiovascular field is limited. As Vesely puts it in his review with regard to heart valves: "The failure of this approach is much less dramatic [than the decellularized valve], as apparently none of these scaffolds have been tried in patients." This is actually not true for the blood vessel field, since a Japanese group reported a series of apparently successful implantations of tissue-engineered vascular grafts in the pulmonary artery position (Shin'oka *et al.*, 2003, 2005). They used a polyglycolic acid (PGA) sheet for mechanical reinforcement and a polycaprolactone-poly(lactic acid) copolymer and seeded it with endothelial cells from a peripheral vein or, more recently, directly at the time of surgery with bone marrow cells. Since these experiments were done directly in patients, mechanical details and the long-term performance of these grafts remain unknown.

A principal problem of the polymer approach is that it is difficult to find the right balance between premature polymer degradation, with the risk of rupture (of a blood vessel or valve), and too little degradation, preventing tissue formation. For example, the early experiments with cardiac myocytes seeded on gelatine (Li *et al.*, 1999), alginate (Leor *et al.*, 2000), or PGA (Bursac *et al.*, 1999) showed survival of cells just on the surface of the matrix, suggesting that these scaffold materials prevented rather than promoted tissue formation. Much effort is directed toward newer matrix materials that may overcome the current limitations. Material sciences and particularly nanotechnology are

progressing rapidly, and it may be that in a collaboration between engineers, physicists, biotechnologists, biologists, and morphologists the ideal scaffold material for creating truly artificial heart tissues will be designed (Buxton *et al.*, 2003; M. E. Davis *et al.*, 2005). Recent examples are tubular scaffolds for the engineering of blood vessels that were generated by electrospinning of collagen and elastin (Boland *et al.*, 2004) and collagen tubes for cardiac-tissue engineering (Yost *et al.*, 2004). Another innovative approach is to use MRI-derived three-dimensional images of an organ as a blueprint for the fully automated fabrication of a synthetic copy (Sodian *et al.*, 2005).

### Biopolymers

The third approach is based on the entrapment of the desired cardiovascular cell type in biopolymers such as collagen I and fibrin. These polymers form a gel in which the cells are trapped in a given three-dimensional form. The main advantage of this approach is that both collagen I and fibrin are approved materials in clinical use and apparently promote rather than prevent tissue formation. With this technique Weinberg and Bell (1969) generated blood vessels more than 20 years ago, and in the meantime many groups have adopted a similar approach using fibroblasts or smooth muscle cells to create blood vessels (L'Heureux *et al.*, 1993; Niklason *et al.*, 1999) or heart valves (Vesely, 2005) and cardiac myocytes for myocardial patches (Eschenhagen *et al.*, 1997; van Luyn *et al.*, 2002; Zimmermann *et al.*, 2000). A disadvantage of the biopolymer approach is that, until now, the tensile strength of the resulting tissues has been relatively low. None of it has been clinically applied yet.

### Cell Sheets

The fourth strategy differs from all others in that it goes without any scaffold material. In this approach, first described by Auger's group (L'Heureux *et al.*, 1998), vascular smooth muscle cells were grown on plastic culture dishes as normal monolayers until confluency and were then removed from the culture dish as a cellular sheet and wrapped around a porous mandrel to form the media, nourished from the inside through the mandrel. In the same manner, a second layer of fibroblast sheets was wrapped around the media to form the adventitia. Finally, the mandrel was removed and the tube populated with endothelial cells by installation and rotating overnight. These sheet-based blood vessels exhibit a very good burst pressure, exceeding that of human saphenous veins and vasoactive responses to several known receptor ligands (Laflamme *et al.*, 2006). Recently, sheet-based blood vessels made exclusively from human fibroblasts and human endothelial cells have been tested successfully in nonhuman primates (L'Heureux *et al.*, 2006). In a similar strategy, cardiac myocyte sheets can be stapled to form a contracting myocardial tissue (Shimizu *et al.*, 2002).

## V. STATE OF MYOCARDIAL-TISSUE ENGINEERING

### Heartlike Tissue Structure

Early experiments with biodegradable polymer scaffolds such as polyglycolic acid, alginate, and preformed collagen sponges showed that cardiac cells survive on these preformed three-dimensional structures but do not form synchronously beating, force-developing, heartlike structures (Bursac *et al.*, 1999; Leor *et al.*, 2000; Li *et al.*, 1999), likely because the scaffolds prevented the intense cell-cell contacts necessary for tissue formation. In contrast, tissue-engineering approaches based on biopolymers such as liquid collagen +/- Matrigel hydrogels or prefabricated collagen sponges + Matrigel as well as a cell sheet technique yielded spontaneously contracting myocardial tissues that exhibit a characteristic cardiac musclelike structure, both on the cellular and subcellular levels (Eschenhagen *et al.*, 1997; Radisic *et al.*, 2004; Shimizu *et al.*, 2002; van Luyn *et al.*, 2002) (Fig. 82.1). All of these approaches make use of the intrinsic capacity of immature cardiac cells to form heartlike muscle structures spontaneously (Akins *et al.*, 1999; Moscona and Moscona, 1952) that can be directed and enhanced by mechanical load (Eschenhagen *et al.*, 1997; Fink *et al.*, 2000), electrical stimulation (Radisic *et al.*, 2004), oxygenation and perfusion (Radisic *et al.*, 2005; Zimmermann *et al.*, 2006), growth factors (Zimmermann *et al.*, 2002b), and a native heart cell mix (Naito *et al.*, 2006). Thus, on a small scale, true heart muscle patches can be engineered from primary heart cells.

### Contractile Function

Such tissue-engineered heart muscle patches beat spontaneously and develop contractile force. Reported values range between 0.05 and 2 mN/mm<sup>2</sup> (Eschenhagen and Zimmermann, 2005), which is still considerably lower than the biological limit of 50 mN/mm<sup>2</sup>. Under optimized culture conditions, including high oxygen, insulin, and auxotonic stretch plus electrical stimulation, EHTs develop up to 5 mN/mm<sup>2</sup> (own unpublished data). The remaining difference from native heart muscle is likely due to several factors: (1) The occupancy of the EHT tissue by muscle tissue is relatively low (<30% vs. almost 100%); (2) cardiac myocytes in EHTs are thinner when compared to the thick, bricklike adult cardiac myocytes of the ventricle; (3) orientation is not always perfectly parallel; and (4) the developmental state of the myocytes does not reach the level of terminal differentiation, as seen from the relatively high fraction of slow  $\beta$ -myosin heavy chain when compared to fast  $\alpha$ -myosin heavy chain. Whereas such features clearly distinguish tissue-engineered patches from native myocardium, it is questionable whether, for the purpose of cardiac repair, a higher degree of maturation would be helpful. Immature cells have a higher remodeling capacity and resistance to

**FIG. 82.1.** Current approaches to myocardial-tissue engineering. **(A)** Macroscopic view of the setup to cast, culture, phasically stretch, and measure the contractile force of engineered heart tissue (EHT) based on collagen I/Matrigel hydrogels (Zimmermann *et al.*, 2002b). **(B)** Macroscopic (top) and microscopic view (H&E stain bottom) of stacked monolayers forming a beating three-dimensional tissue (Shimizu *et al.*, 2002). **(C)** Tissue formation (H&E stain, top) and sarcomere structure (bottom) in electrically stimulated collagen I + Matrigel-based constructs (Ultrafoam sponges) seeded with neonatal rat heart cells (Radisic *et al.*, 2004).

hypoxia [ $\text{Po}_2$  in the fetus 20–25 mmHg; (Hollenberg *et al.*, 1976)], both could be critical parameters for integration into the host myocardium. Moreover, there is experimental evidence that myocytes undergo further maturation after implantation (Zimmermann *et al.*, 2002a). The heart of a neonatal rat weighs approximately 30 mg and that of an adult rat 1000 mg. This increase is due almost entirely to an increase in size and not number, meaning that the volume of myocytes increases 30-fold from neonatal to adult. If the same applies to cardiac myocytes in EHTs before and after implantation, the aforementioned ideal patch of 45 g could develop from an implanted patch of 1.5 g, a much more realistic number. Thus, it appears possible that the loose network of myocytes in EHTs at time of implantation form a much larger, compact muscle tissue with an adult structural and functional phenotype over time. Recent findings in rats four weeks after implantation support this assumption (Zimmermann *et al.*, 2006).

### Directed Process of Manufacturing

Currently, the most defined techniques to produce engineered myocardial patches for cardiac repair are (1) cell seeding on collagen/Matrigel sponges (Radisic *et al.*, 2004), (2) generation of collagen I/Matrigel-based EHTs (Zimmermann *et al.*, 2002b), and (3) the cell sheet technique (Shimizu *et al.*, 2002). All three techniques can be scaled up

in terms of width and length but, for the reasons discussed earlier, not yet in thickness. Scale-up and clinical application will also require some automation, but this appears possible with either technique and has actually already been established for the cell sheet technology (personal communication, T. Shimizu). Others generate cardiospheres (Akins *et al.*, 1999) or spheric microtissues (Kelm *et al.*, 2006) and implant them, but here cells are not under directed mechanical load and therefore are not well oriented and cannot be handled as a tissue patch. Thus, it is not clear whether these spheres have an advantage as compared to cells implanted in the heart as a suspension.

### Critical Size and Vascularization

The usual size of currently developed engineered myocardial tissue is in the range of centimeters in width/length and 0.1 to 1–4 millimeters in thickness (reviewed in Eschenhagen and Zimmermann, 2005). While the width and length can be expanded indefinitely, the thickness of compact myocardial tissue is limited in all models to 50–100  $\mu\text{m}$ . This value may be enhanced by perfusion and high oxygen to a maximal theoretical thickness of 200  $\mu\text{m}$  (Radisic *et al.*, 2005), but more seems unlikely to be achievable in the absence of vascularization and internal perfusion. A recent study demonstrated that multiloop EHTs of an initial size of approximately  $15 \times 15 \times 4$  mm formed a compact new layer

of myocardium at a mean thickness of 0.5 mm when implanted onto infarcted rat hearts (Zimmermann *et al.*, 2006). Yet this is still far away from the thickness of the walls of the normal human left ventricle (mean 9 mm), and it is very likely that true vascularization is necessary to approach such values. One idea to vascularize tissue-engineered myocardium may be to support vascular ingrowth from adjacent or embedded vessels, either *in vitro* (Kofidis *et al.*, 2003) or *in vivo* (Shimizu *et al.*, 2006). Finally, some hope is related to the observation that primitive vascular structures develop spontaneously in EHTs (Zimmermann *et al.*, 2002b) (as in skeletal muscle constructs; Levenberg *et al.*, 2005). These vessels appear to find contact with the host vasculature after implantation (Zimmermann *et al.*, 2006). The angiogenic process could be further enhanced by other biological means, including angiogenic growth factors, but it is not clear at this point whether it helps to form thicker cardiac tissues *in vitro*.

### Electrical Integration and Improvement of Function After Implantation

Available data suggest that engineered sandwich constructs (Furuta *et al.*, 2006) and EHTs (Zimmermann *et al.*, 2006) find electrical contact with the host myocardium after implantation. This is in accordance with very careful studies of isolated cardiac myocytes injected directly into the myocardium (Rubart *et al.*, 2003). However, studying the question in engineered constructs implanted not in but onto the heart surface is not trivial and is difficult to substantiate (Eschenhagen *et al.*, 2006). Optical imaging with voltage-sensitive dyes and electrical mapping experiments suggest undelayed impulse propagation through the graft, but it is not entirely clear how the electrical contact is actually made between graft and host. Histological analyses did not unequivocally reveal cell-cell contacts in the respective zones (Furuta *et al.*, 2006; Zimmermann *et al.*, 2006), and high-resolution two-photon imaging (Rubart *et al.*, 2003) has not yet been performed in these models. Thus, at present it cannot be excluded that some of the apparently normal impulse propagation is due to electrotonic contact or even via fibroblasts. Present experiments with engineered heart tissues revealed no evidence for proarrhythmic effects (Zimmermann *et al.*, 2006). Yet the grafts can depolarize spontaneously, at least at the time of implantation, and this represents principally an arrhythmogenic risk. One reason this was not observed may be that, in the moment the engineered tissue couples to the host myocardium, it is overpaced by the higher frequency of the rat sinus rhythm. Finally, the rodent heart is not the most suited arrhythmia model, and more data are necessary to clarify this issue.

Several animal and human studies have suggested that cells of various origins when injected into the heart after myocardial infarction can have beneficial effects on contractile function (Dimmeler *et al.*, 2005; Laflamme and Murry, 2005; Murry *et al.*, 2002; Nadal-Ginard *et al.*, 2003).

The underlying mechanisms remain largely unknown but most likely do not include the formation of new contracting myocardium. Tissue-engineered myocardial patches, in contrast, are true heart muscles and should add new contracting units to the injured heart when implanted. Thus, engineered patches should have an effect on myocardial contractility that exceeds that of cell injections. Early studies actually reported some beneficial effects of implanting alginate (Leor *et al.*, 2000) or gelatine-based constructs (Li *et al.*, 1999) onto the heart, but these studies were not powered to quantify functional changes. We have recently performed a large-scale study in rats in which multiloop EHTs were implanted above the infarct scar 14 days after ligation of the left anterior descending (LAD) coronary artery (Fig. 82.2) (Zimmermann *et al.*, 2006). This study showed for the first time that tissue-engineered heart muscles can indeed restore contraction of an infarcted ventricular wall, improve ejection fraction in those animals with a poor function before implantation, and prevent further dilatation. Despite these encouraging results, it should be noted that even the implantation of a relatively large (surface approximately 1 cm<sup>2</sup>) and thick (~1–4 mm) patch with nominally 12 million heart cells for a 1-g rat heart did not restore normal function. Importantly, however, control patches with noncontractile or fixed cells induced no major beneficial effects, supporting the notion that the improvement of systolic and diastolic function indeed derived from the cardiac myocytes in the EHT. Thus, the study may serve as a proof of principle for this approach.

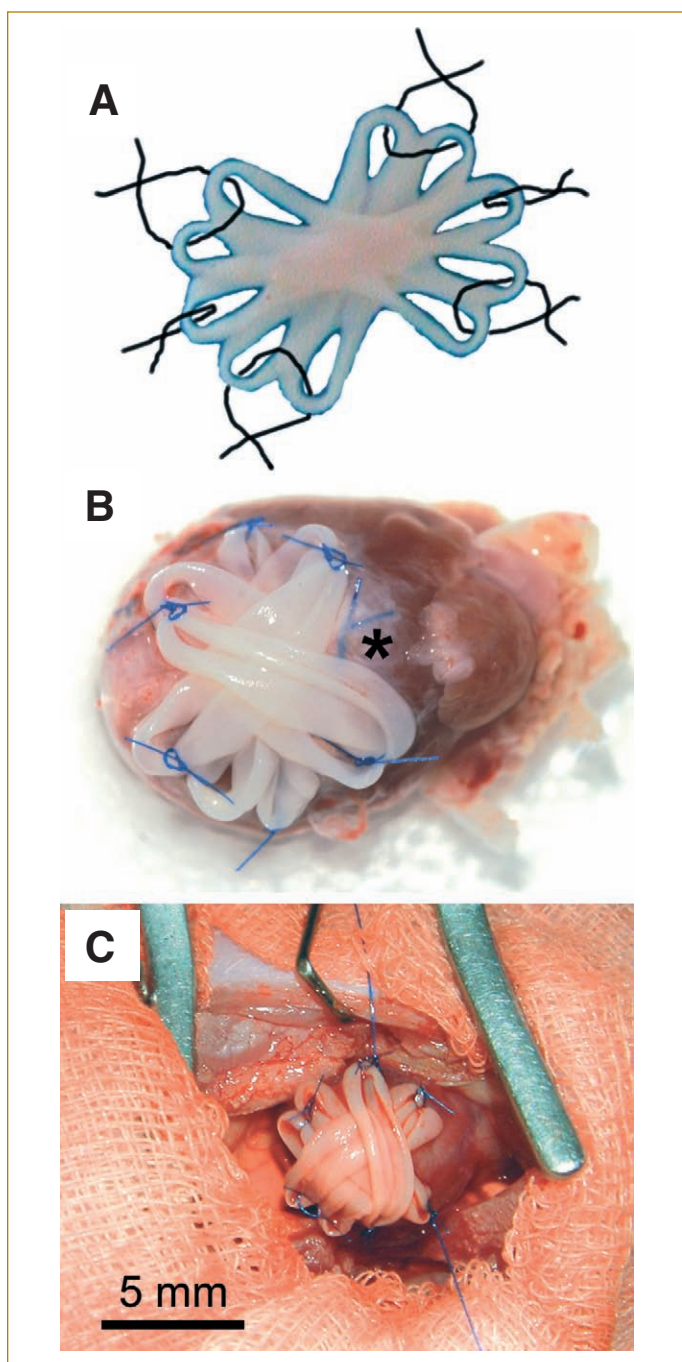

### Autologous Patch

Tissue engineering at present utilizes almost exclusively allogeneic cardiac cells from neonatal rat or mouse or embryonic chick hearts. Accordingly, implantation studies used either immune-deficient models such as nude rats or mice (Furuta *et al.*, 2006; Shimizu *et al.*, 2002) or pharmacological immunosuppression (Zimmermann *et al.*, 2002a, 2006). The impact of these conditions on graft integration is unknown. A recent report describes a technique to generate EHTs from mouse embryonic stem cell-derived cardiomyocytes (Guo *et al.*, 2006), but this is also an allogeneic approach. The reason for the lack of autologous tissue-engineering approaches is simply that, until today, no one has identified a suitable adult stem cell source that allows allocation of sufficient numbers of true cardiac myocytes. Several reports have indicated that such stem cells exist in the heart (A. P. Beltrami *et al.*, 2003; Laugwitz *et al.*, 2005; Oh *et al.*, 2003), but these exciting new data have not yet been translated into tissue engineering.

### Scale-Up of GMP and GLP

Clinical application of tissue-engineered myocardial patches requires means to scale up the procedure under the strict regulations of good manufacturing (GMP) and laboratory practice (GLP). Although this question may appear far

**FIG. 82.2.** EHT grafting onto infarcted rat heart. (A) Multiloop EHT with sutures before implantation. (B) Rat heart with multiloop EHTs sutured onto an infarcted rat heart *ex vivo*. (C) Rat heart situs showing a heart with a multiloop EHT fixed with six single-knot sutures placed in healthy myocardium just adjacent to the infarct scar through a left lateral thoracotomy.

away from the current state of the field, the technical effort and thus the costs will be important for the clinical success of a given technique. The cell sheet technique, seeding of collagen sponges, and the EHT technologies can be automated and performed in GMP/GLP facilities without

principal problems. However, the regulations of GMP/GLP do not permit the use of animal sera and growth supplements at any given point of the manufacturing process. Some progress has recently been made in defining serum-free and essentially Matrigel-free conditions for EHTs (Naito *et al.*, 2006), but more has to be done.

## VI. BOTTLENECKS

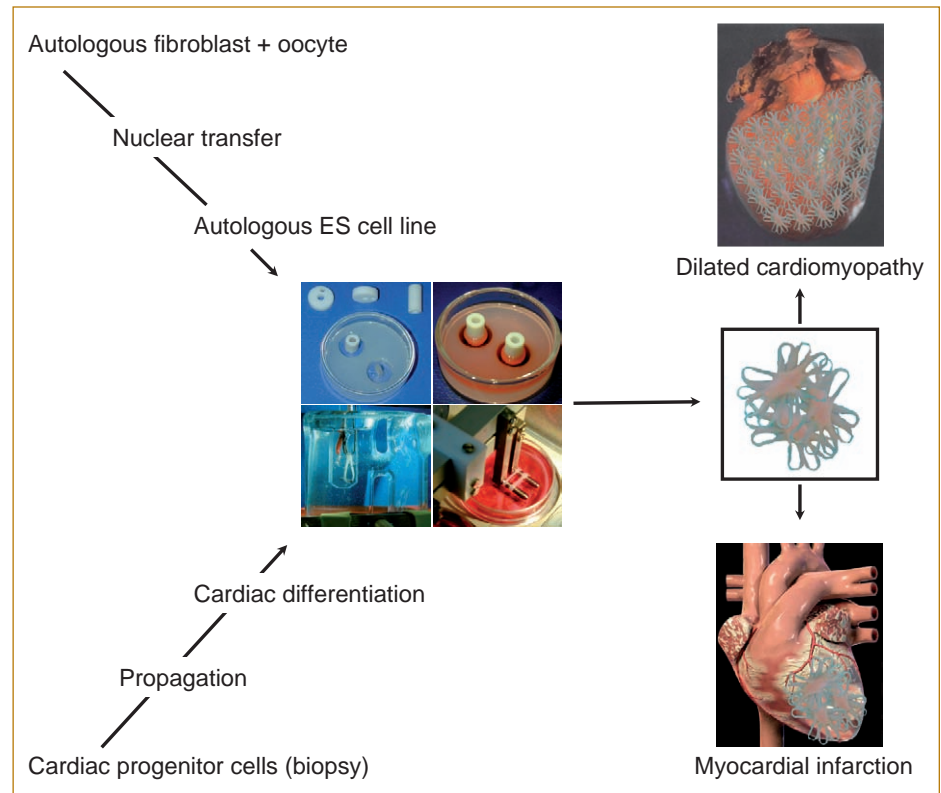

The critical bottlenecks in tissue engineering of heart valves, vessels, and myocardial patches differ. For a detailed review of the two former fields, the reader is referred to recent papers (Isenberg *et al.*, 2006; Vesely, 2005). It appears that the main hurdle for tissue-engineered heart valves is the relatively good performance of conventional prostheses and the disastrous consequences of any failure. Very encouraging progress has been made with tissue-engineered blood vessels, particularly with the sheet-based technique. In contrast to the myocardial patch, neither a suitable autologous cell source nor a sufficient size is a critical issue in this area. Recent sheet-based blood vessels exhibited excellent burst strength and compliance and, in rats and nonhuman primates, excellent long-term patency rates (L'Heureux *et al.*, 2006). Whether this also applies in humans is currently being tested. The long generation time (28 weeks) presently precludes urgent clinical use, but this is not a major drawback to these exciting new data.

Myocardial-tissue patches require less mechanical strength than vessels and valves, because they will be, with the exception of congenital malformations, likely applied as an add-on to an infarcted or failing heart. This also makes potential failure less dramatic. On the other hand, the lack of a suitable human cardiomyocyte source and the problem of critical size are the reasons why myocardial-tissue engineering is still far from any clinical application. Other problems, including scale-up, GMP/GLP- and serum-free culture conditions, and optimization of scaffolds can likely be solved by technical means. Electrical integration is subject to intense research, and increasing evidence suggests that myocardial grafts integrate well into the host myocardium.

## Cell Source

The most obvious problem is the identification of a suitable cell source. Since cardiac myocytes do not divide at a relevant rate, only two sources can be envisioned: (1) human adult stem cells (Beltrami *et al.*, 2003; Laugwitz *et al.*, 2005; Messina *et al.*, 2004; Oh *et al.*, 2003) and (2) human embryonic stem cells (Kehat *et al.*, 2001). The main advantage of the former is its autologous character, i.e., that the cells could ideally be taken from patient biopsies, amplified *ex vivo*, differentiated into cardiac myocytes, and used to engineer a myocardial-tissue patch that would be recognized by the patient's immune system as autologous. The crucial open questions are whether such cells exist in the body at a rate that realistically allows harvesting and amplification, whether they can generate a relevant number of true

**FIG. 82.3.** Perspectives of cardiac-tissue engineering exemplified with the EHT technology. Constructs will be made from ES cells that are ideally autologous, and derived from a nuclear transfer strategy or from adult cardiac progenitors that may be obtained from a heart muscle biopsy. For cardiac regeneration, several circular constructs can be woven together to form a multiloop construct. Several multiloop constructs together can form large “chain mail”-like networks for the treatment of dilated cardiomyopathy or a patch for the treatment of myocardial infarction.

cardiac myocytes, and whether one can produce engineered tissues from such cells. Extensive research is currently directed to solve these questions. The main advantage of human ES cells is that they unambiguously generate true cardiac myocytes (and many other cell types). Thus, improving the efficacy of cardiac myocyte differentiation will be essential to render ES cell-based tissue engineering feasible. The main disadvantage, however, is that ES cell-derived engineered tissues are allogeneic; i.e., their implantation would require life-long immunosuppression. Moreover, undifferentiated ES cells can form teratomas (Laflamme and Murry, 2005). Finally, legislative restrictions exist in many countries that, at present, represent hurdles in this part of research. The recent identification of multipotent adult germ-line stem cells from mouse testis with properties of ES cells (Guan *et al.*, 2006) opens an interesting perspective for an autologous cell source for myocardial-tissue engineering, at least for male patients. Finally, it is difficult to predict today which cell type will finally work, and therefore research to this end should be as broad and unprejudiced as possible.

### Size/Vascularization

Size truly matters, and it is possible that a sufficient size of an engineered tissue patch turns out to be the second most critical bottleneck. As outlined earlier, a realistic patch to improve heart function after myocardial infarction needs a surface of several square centimeters and a thickness of

millimeters and consists of several hundred million cardiac myocytes. This number of cells can only be provided by scale-up of stem cell cultures and directing stem cell differentiation into the cardiac lineage. But even with these cell numbers at hand, it will be a major task to generate myocardial tissues with a thickness of several millimeters. A combination of cardiac-muscle engineering principles and means to induce vascularization *in vitro* will be necessary to solve this problem. A possible scenario is to create a loose network of patches and to implant them on the heart as a biological ACORN device (Fig. 82.3).

## VII. SUMMARY

Tissue engineering of heart valves, small-diameter blood vessels, and myocardial patches is an exciting field with great clinical potential. The concerted research activity of several disciplines in the biomedical and engineering fields has yielded significant progress, but it still remains a major challenge to reproduce or at least approach the exquisite natural design of any of the cardiovascular structures and to translate such concepts to the clinic. With the exception of some rather premature implantations of unfixed, decellularized heart valves and cell-coated synthetic polymer conduits in children, tissue-engineered cardiovascular products have not entered the clinical arena yet. This seems wise, given the catastrophic consequences of failure in the case of a heart valve or a coronary artery.

But how can cardiovascular products make the step from the bench to the clinic? Rigorous *in vitro* testing and comprehensive small- and large-animal experiments are certainly necessary. Yet it is questionable whether this can prevent clinical failure. Once a tissue-engineering product has advanced to the large-animal testing stage, it becomes a matter of using the right model that ideally simulates human physiology and responsiveness to the respective intervention. This problem has been especially evident in large-animal valve trials. Sheep tend to develop massive fibrosis, which can be misleading in two respects — overestimation of the risk of valve degeneration, but also underestimation of mechanical instability because the fibrosis has in fact stabilizing effects on the valve (Schoen, 1998; Vesely, 2005). Pigs show a high level of calcification. Eventually, primates seem to be an ideal test bed. However, investigator-driven studies originating from academia are unlikely to be

able to pay for these ultimate trials. On the other hand, industry will invest only if they sense a relevant profit based on successful preclinical data, leaving the field in a deadlocked situation. Thus, the only possible way to advance tissue engineering is to rigorously test available and new concepts in small-animal models and to advance the most promising into large-animal trials. Once a successful transition has been made into the clinic, it will be more likely that industry will finally be attracted by the field.

From all of the available data on cardiovascular-tissue engineering, it seems that tissue-engineered blood vessels have a good chance to be the first tissue-engineered products with a real practical value. The perspective of tissue-engineered valves will likely be restricted to children. Myocardial patches have a long way to go before they will be applied in humans, and their success will depend mainly on advances in stem cell technology.

### I. INTRODUCTION

Human organs are exposed to a variety of possible injuries from the time the fetus develops. Individuals may suffer from congenital disorders, cancer, trauma, infection, inflammation, iatrogenic injuries, or other conditions that may lead to organ damage or loss and necessitate eventual reconstruction or replacement. Whenever there is deficient organ function, replacement may be achieved with artificial organs or organ transplantation. These are flawed therapies, however, for artificial organs are not able to replace all physiologic functions and cannot fully integrate functionally into body systems, while organ transplantation is marred by donor shortages and immunologic rejection and requires chronic and morbid medical therapy. In most cases, the replacement of lost or deficient tissues with functionally equivalent autologous tissues would improve the outcome for patients immensely. Tissue-engineering therapies have been developed in order to achieve this goal.

The development of functional organ systems from the building blocks of cells, scaffolding, and growth factors is a Herculean task, however, as evidenced by the few successful tissue-engineering technologies currently in clinical use. An examination of the building blocks of tissue-engineering strategies as well as of the successful applications of these techniques in human clinical applications provides insight into the difficulties facing scientists as they seek to develop more complex bioengineered organs.

### II. TISSUE ENGINEERING: STRATEGIES FOR TISSUE RECONSTITUTION

The field of regenerative medicine encompasses various areas of technology, such as tissue engineering, stem cells, and cloning. One of the major components of regenerative medicine, tissue engineering, follows the principles of cell transplantation, materials science, and engineering toward the development of biological substitutes that can restore and maintain normal function. Tissue-engineering strategies generally fall into three categories: the use of acellular matrices (where matrices are used alone and which depend on the body's natural ability to regenerate for proper orientation and direction of new tissue growth), the use of simple cells, and the use of matrices combined with cells. The main obstacles that must be overcome for the clinical application of these strategies are localizing reliable, immunocompatible cell sources, developing biocompatible and functional scaffolding, and providing growth factors and vascularization for bioengineered organs.

Acellular tissue matrices are usually prepared by manufacturing artificial scaffolds or by removing cellular components from tissues via mechanical and chemical manipulation to produce collagen-rich matrices (Dahms *et al.*, 1998; Piechota *et al.*, 1998; Yoo *et al.*, 1998b; Chen *et al.*, 1999). These matrices tend to degrade slowly on implantation and are generally replaced by the extracellular

matrix (ECM) proteins that are secreted by the ingrowing cells. Cells can be used in combination with scaffolds or injected as simple cell therapy, either with carriers (such as hydrogels) or alone (Atala, 2006).

### III. CELL SOURCES

When cells are used for tissue engineering, a small piece of donor tissue must be harvested and dissociated into individual cells. These cells are either implanted directly into the host or expanded in culture, attached to a support matrix, and then reimplanted into the host after expansion. The source of donor tissue can be heterologous (such as bovine), allogeneic (same species, different individual), or autologous. Ideally, both structural and functional tissue replacement will occur with minimal complications. The most preferred cells to use are autologous cells, where a biopsy of tissue is obtained from the host, the cells are dissociated and expanded in culture, and the expanded cells are implanted into the same host (Atala *et al.*, 1993, 1994; Cilento *et al.*, 1994; Yoo and Atala, 1997; Fauza *et al.*, 1998a, 1998b; Yoo *et al.*, 1998a, 1998b; Amiel and Atala, 1999; Kershen and Atala, 1999; Oberpenning *et al.*, 1999; Park *et al.*, 1999; Godbey and Atala, 2002). The use of autologous cells, although it may cause an inflammatory response, avoids rejection, and thus the deleterious side effects of immunosuppressive medications can be avoided.

One of the limitations of applying cell-based regenerative medicine techniques toward organ replacement has been the inherent difficulty of growing specific cell types in large quantities. Even when some organs, such as the liver, have a high regenerative capacity *in vivo*, cell growth and expansion *in vitro* may be difficult. By studying the privileged sites for committed precursor cells in specific organs as well as by exploring the conditions that promote differentiation, one may be able to overcome the obstacles that could lead to cell expansion *in vitro*. For example, urothelial cells could be grown in the laboratory setting in the past, but only with limited expansion. Several protocols were developed since the mid-1980s that identified the undifferentiated cells and kept them undifferentiated during their growth phase (Cilento *et al.*, 1994; Liebert *et al.*, 1997; Scriven *et al.*, 1997; Puthenveetil *et al.*, 1999). Using these methods of cell culture, it is now possible to expand a urothelial strain from a single specimen that initially covers a surface area of 1 cm<sup>2</sup> to one covering a surface area of 4202 m<sup>2</sup> (the equivalent area of one football field) within eight weeks (Cilento *et al.*, 1994). These studies indicated that it should be possible to collect autologous bladder cells from human patients, expand them in culture, and return them to the human donor in sufficient quantities for reconstructive purposes (Cilento *et al.*, 1994; Harriss, 1995; Freeman *et al.*, 1997; Liebert *et al.*, 1997; Lobban *et al.*, 1998; Nguyen *et al.*, 1999; Rackley *et al.*, 1999). Major advances have been achieved since the mid-1990s on the possible expansion of a variety of primary human cells, with specific techniques that

make the use of autologous cells possible for clinical application.

An area of concern in the field of tissue engineering in the past was the source of cells for regeneration. The concept of creating engineered constructs involves initially obtaining cells for expansion from the diseased organ. A study recently showed that cultured neuropathic bladder smooth muscle cells possess and maintain different characteristics than normal smooth muscle cells *in vitro*, as demonstrated by growth assays, contractility, and adherence tests *in vitro* (Lin *et al.*, 2004). However, when neuropathic smooth muscle cells were cultured *in vitro* and seeded onto matrices and implanted *in vivo*, the tissue-engineered constructs showed the same properties as those tissues engineered with normal cells (Lai *et al.*, 2002). It is known that genetically normal progenitor cells, which are the reservoirs for new cell formation, are programmed to give rise to normal tissue, regardless of whether the niche resides in normal or diseased tissues. The stem cell niche and its role in normal tissue regeneration remain a fertile area of ongoing investigation.

### IV. ALTERNATE CELL SOURCES

#### Stem Cells

Most current strategies for tissue engineering depend on a sample of autologous cells from the diseased organ of the host. However, for many patients with extensive end-stage organ failure, a tissue biopsy may not yield enough normal cells for expansion and transplantation. In other instances, primary autologous human cells cannot be expanded from a particular organ, such as the pancreas. In these situations, pluripotent human embryonic stem cells are envisioned as a viable source of cells, because they can serve as an alternative source of cells from which the desired tissue can be derived.

Human embryonic stem cells exhibit two remarkable properties: the ability to proliferate in an undifferentiated but pluripotent state (self-renew), and the ability to differentiate into many specialized cell types (Brivanlou *et al.*, 2003). They can be isolated by immunosurgery from the inner cell mass of the embryo during the blastocyst stage (five days postfertilization) and are usually grown on feeder layers consisting of mouse embryonic fibroblasts or human feeder cells (Richards *et al.*, 2002). More recent reports have shown that these cells can be grown without the use of a feeder layer (Amit *et al.*, 2003), thus avoiding the exposure of these human cells to mouse viruses and proteins. These cells have demonstrated longevity in culture by maintaining their undifferentiated state for at least 80 passages when grown using current published protocols (Thomson *et al.*, 1998; Reubinoff *et al.*, 2000).

Human embryonic stem cells have been shown to differentiate into cells from all three embryonic germ layers *in vitro*. Skin and neurons have been formed, indicating

ectodermal differentiation (Schuldiner *et al.*, 2000; Reubinoff *et al.*, 2001; Schuldiner *et al.*, 2001). Blood, cardiac cells, cartilage, endothelial cells, and muscle have been formed, indicating mesodermal differentiation (Kaufman *et al.*, 2001; Kehat *et al.*, 2001; Levenberg *et al.*, 2002). Pancreatic cells have also been formed, indicating endodermal differentiation (Assady *et al.*, 2001). In addition, as further evidence of their pluripotency, embryonic stem cells can form embryoid bodies, which are cell aggregations that contain all three embryonic germ layers, while in culture and can form teratomas *in vivo* (Itskovitz-Eldor *et al.*, 2000).

Adult stem cells have the advantage of avoiding the ethical issues associated with embryonic cells, and they also do not transdifferentiate spontaneously to a malignant phenotype. The use of adult stem cells is limited for clinical therapy due to the difficulties encountered with cell expansion to large quantities.

Fetal stem cells derived from amniotic fluid and placentas have recently been described and represent a novel source of stem cells. The cells express markers consistent with human embryonic stem cells, such as OCT4 and SSEA-4, but do not form teratomas and do not spontaneously transdifferentiate to a malignant phenotype. The cells are multipotent and are able to differentiate into all three germ layers. In addition, the cells have a high replicative potential and could be stored for future self-use, without the risks of rejection and without ethical concerns (Lanza *et al.*, 1999).

## V. THERAPEUTIC CLONING

While there has been tremendous interest in the field of nuclear cloning since the birth of Dolly in 1997, the first successful nuclear transfer was reported over 50 years ago by Briggs and King (Briggs and King, 1952), cloned frogs which were the first vertebrates derived from nuclear transfer, were subsequently reported by Gurdon in 1962, but the nuclei were derived from nonadult sources (Gordon, 1962). In the past several years, tremendous advances in nuclear cloning technology have been reported, indicating the relative immaturity of the field. Dolly was not the first cloned mammal to be produced from adult cells; in fact, live lambs were produced in 1996 using nuclear transfer and differentiated epithelial cells derived from embryonic discs (Campbell *et al.*, 1996). The significance of Dolly was that she was the first mammal to be derived from an adult somatic cell using nuclear transfer (Wilmut *et al.*, 1997). Since then, animals from several species have been grown using nuclear transfer technology, including cattle (Cibelli *et al.*, 1998), goats (Baguisi *et al.*, 1999; Keefer *et al.*, 2002), mice (Wakayama *et al.*, 1998), and pigs (De Sousa *et al.*, 2002).

Two types of nuclear cloning, reproductive cloning and therapeutic cloning, have been described, and a better understanding of the differences between the two types may help to alleviate some of the controversy that surrounds these technologies. Banned in most countries for human

applications, reproductive cloning is used to generate an embryo that has the identical genetic material as its cell source. This embryo can then be implanted into the uterus of a female to give rise to an infant that is a clone of the donor. On the other hand, therapeutic cloning is used to generate early-stage embryos that are explanted in culture to produce embryonic stem cell lines whose genetic material is identical to that of its source. These autologous stem cells have the potential to become almost any type of cell in the adult body and thus would be useful in tissue- and organ-replacement applications (Hochedlinger and Jaenisch, 2003). Therefore, therapeutic cloning, which has also been called *somatic cell nuclear transfer*, may provide an alternative source of transplantable cells. According to data from the Centers for Disease Control, it has been estimated that approximately 3000 Americans die every day of diseases that could have been treated with stem cell-derived tissues (Thomson *et al.*, 1998). With current allogeneic tissue transplantation protocols, rejection is a frequent complication because of immunologic incompatibility, and immunosuppressive drugs must be administered to treat and hopefully prevent host-versus-graft disease (Lanza *et al.*, 2001). The use of transplantable tissue and organs derived from therapeutic cloning may potentially lead to the avoidance of immune responses that typically are associated with transplantation of nonautologous tissues (Lanza *et al.*, 1999).

While promising, somatic cell nuclear transfer technology has certain limitations that require further improvements before therapeutic cloning can be applied widely in replacement therapy. Currently, the efficiency of the overall cloning process is low. The majority of embryos derived from animal cloning do not survive after implantation (Solter, 2000; Rideout *et al.*, 2001; Hochedlinger and Jaenisch, 2002). In practical terms, multiple nuclear transfers must be performed in order to produce one live offspring for animal-cloning applications. The potential for cloned embryos to grow into live offspring is between 0.5 and 18% for sheep, bovine, pigs, and mice (Tsunoda and Kato, 2002). However, greater success (80%) has been reported in cattle (Kato, *et al.*, 1998), which may be due in part to the availability of advanced bovine-supporting technologies, such as *in vitro* embryo production and embryo transfer, which have been developed for this species for agricultural purposes. To improve cloning efficiencies, further improvements are required in the multiple complex steps of nuclear transfer, such as enucleation and reconstruction, activation of oocytes, and cell-cycle synchronization between donor cells and recipient oocytes, that will more readily produce viable sources of cells.

Furthermore, common abnormalities have been found in newborn clones if they survive to birth, including enlarged size with an enlarged placenta (*large-offspring syndrome*) (Young *et al.*, 1998), respiratory distress and defects of the kidney, liver, heart, and brain (Cibelli *et al.*, 2002), obesity

(Tamashiro *et al.*, 2002), and premature death (Ogonuki *et al.*, 2002). These may be related to the epigenetics of the cloned cells, which involve the reversible modifications of the DNA or chromatin while the original DNA (genetic) sequences remain intact. Faulty epigenetic reprogramming in clones, where the DNA methylation patterns, histone modifications, and overall chromatin structure of the somatic nuclei are not being reprogrammed to an embryonic pattern of expression, may explain the aforementioned abnormalities (Hochedlinger and Jaenisch, 2003). Reactivation of key embryonic genes at the blastocyst stage is usually not present in embryos cloned from somatic cells, while embryos cloned from embryos consistently express early embryonic genes (Boiani *et al.*, 2002; Bortvin *et al.*, 2003). Proper epigenetic reprogramming to an embryonic state may help to improve the cloning efficiency and reduce the incidence of abnormal cloned cells.

## VI. BIOMATERIALS

For cell-based tissue engineering, once cells have been cultured and expanded, they are seeded onto a scaffold synthesized using the appropriate biomaterial. In tissue engineering, biomaterials replicate the biologic and mechanical functions of the native extracellular matrix (ECM) found in tissues in the body by serving as an artificial ECM. As a result, biomaterials provide a three-dimensional space for the cells to form into new tissues with appropriate structure and function and also can allow for the delivery of cells and appropriate bioactive factors (e.g., cell adhesion peptides, growth factors) to desired sites in the body (Kim and Mooney, 1998). Because the majority of mammalian cell types are anchorage dependent and will die if no cell adhesion substrate is available, biomaterials provide a cell adhesion substrate that can deliver cells to specific sites in the body with high loading efficiency. Biomaterials can also provide mechanical support against *in vivo* forces such that the predefined three-dimensional structure is maintained during tissue development. Furthermore, bioactive signals, such as cell adhesion peptides and growth factors, can be loaded along with cells to help regulate cellular function.

The ideal biomaterial should be biocompatible, in that it is biodegradable and bioresorbable to support the replacement of normal tissue without inflammation. Incompatible materials are destined for an inflammatory or foreign-body response that eventually leads to rejection and/or necrosis. In addition, the degradation products, if produced, should be removed from the body via metabolic pathways at an adequate rate that keeps the concentration of these degradation products in the tissues at a tolerable level (Bergsma *et al.*, 1995). Furthermore, the biomaterial should provide an environment in which appropriate regulation of cell behavior (e.g., adhesion, proliferation, migration, and differentiation) can occur such that functional tissue can form. Cell behavior in the newly formed tissue has been shown to

be regulated by multiple interactions of the cells with their microenvironment, including interactions with cell adhesion ligands (Hynes, 1992) and with soluble growth factors. In addition, biomaterials provide temporary mechanical support that allows the tissue to grow in three dimensions while the cells undergo spatial tissue reorganization. The properly chosen biomaterial should allow the engineered tissue to maintain sufficient mechanical integrity to support itself in early development, while in late development it should begin degradation such that it does not hinder further tissue growth (Kim and Mooney, 1998).

Generally, three classes of biomaterials have been utilized for engineering tissues: naturally derived materials (e.g., collagen and alginate), acellular tissue matrices (e.g., bladder submucosa and small intestinal submucosa), and synthetic polymers [e.g., polyglycolic acid (PGA), polylactic acid (PLA), and poly(lactic-co-glycolic acid) (PLGA)]. These classes of biomaterials have been tested with respect to their biocompatibility (Pariante *et al.*, 2001, 2002). Naturally derived materials and acellular tissue matrices have the potential advantage of biological recognition. However, synthetic polymers can be produced reproducibly on a large scale with controlled properties of their strength, degradation rate, and microstructure.

Collagen is the most abundant and ubiquitous structural protein in the body and can be readily purified from both animal and human tissues with an enzyme treatment and salt/acid extraction. Collagen implants degrade through a sequential attack by lysosomal enzymes. Controlling the density of the implant and the extent of intermolecular cross-linking can regulate the *in vivo* resorption rate. The lower the density, the greater the interstitial space and generally the larger the pores for cell infiltration, leading to a higher rate of implant degradation. Collagen contains cell-adhesion-domain sequences (e.g., RGD) that exhibit specific cellular interactions. This may assist in retaining the phenotype and activity of many types of cells, including fibroblasts (Silver and Pins, 1992) and chondrocytes (Sams and Nixon, 1995).

Alginate, a polysaccharide isolated from seaweed, has been used as an injectable cell-delivery vehicle (Smidsrod and Skjak-Braek, 1990) and a cell-immobilization matrix (Lim and Sun, 1980), owing to its gentle gelling properties in the presence of divalent ions such as calcium. Alginate is relatively biocompatible and approved by the FDA for human use as wound dressing material. Alginate is a family of copolymers of D-mannuronate and L-guluronate. The physical and mechanical properties of alginate gel are strongly correlated with the proportion and length of the polyguluronate block in the alginate chains (Smidsrod and Skjak-Braek, 1990).

Acellular tissue matrices are collagen-rich matrices prepared by removing cellular components from tissues (Dahms *et al.*, 1998; Piechota *et al.*, 1998; Yoo *et al.*, 1998b; Chen *et al.*, 1999). The matrices are often prepared by mechanical

and chemical manipulation of a segment of tissue. The matrices degrade slowly on implantation and are replaced and remodeled by ECM proteins synthesized and secreted by transplanted or ingrown cells.

Polyesters of naturally occurring  $\alpha$ -hydroxy acids, including PGA, PLA, and PLGA, are widely used in tissue engineering. These polymers have gained FDA approval for human use in a variety of applications, including sutures. The ester bonds in these polymers are hydrolytically labile, and these polymers degrade by nonenzymatic hydrolysis. The degradation products of PGA, PLA, and PLGA are non-toxic, natural metabolites and are eventually eliminated from the body in the form of carbon dioxide and water. The degradation rate of these polymers can be tailored from several weeks to several years by altering crystallinity, initial molecular weight, and the copolymer ratio of lactic to glycolic acid. Since these polymers are thermoplastics, they can easily be formed into a three-dimensional scaffold with a desired microstructure, gross shape, and dimension by various techniques, including molding, extrusion (Freed *et al.*, 1994), solvent casting, phase separation techniques, and gas-foaming techniques (Harris *et al.*, 1998). Many applications in tissue engineering often require a scaffold with high porosity and ratio of surface area to volume. Other biodegradable synthetic polymers, including poly(anhydrides) and poly(ortho-esters), can also be used to fabricate scaffolds for tissue engineering with controlled properties (Peppas and Langer, 1994).

## VII. GROWTH FACTORS

A key component to scaffold function is the presence of the appropriate growth factors for cell growth and maturation. Growth factors may be produced by cells themselves (autocrine) or by the surrounding environment (paracrine). Scientists have employed various strategies to enhance desirable growth factor production, in order to promote the cell growth and maturation needed for particular organ systems. Some investigators have attempted to influence cell growth factor production with gene therapy, by incorporating genes for growth factor transcription in the transplanted cells. Others have sought to simply inject the growth factors into the cells milieu, but this method often results in rapid dissipation of the agents, due to diffusion (Ikada, 2006).

A novel method of growth factor use in tissue engineering involves the incorporation of growth factors into carriers or cell scaffolds. The goals of these techniques are to provide localized and controlled release of growth factors necessary for cell development. Extensive research is under way to define the exact combination of growth factors needed for specific organ growth and maturation, with an emphasis on the use of these factors to induce more rapid cell development and differentiation, appropriate cell function and orientation, and extracellular matrix development and vascularization (Rosso *et al.*, 2005).

## VIII. VASCULARIZATION

One of the restrictions of the engineering of tissues is that cells cannot be implanted in volumes exceeding 3 mm<sup>3</sup> because of the limitations of nutrition and gas exchange (Folkman and Hochberg, 1973). To achieve the goals of engineering large, complex tissues and possibly internal organs, vascularization of the regenerating cells is essential.

Three approaches have been used for vascularization of bioengineered tissue: (1) incorporation of angiogenic factors in the bioengineered tissue, (2) seeding EC with other cell types in the bioengineered tissue, and (3) prevascularization of the matrix prior to cell seeding. Angiogenic growth factors may be incorporated into the bioengineered tissue prior to implantation, in order to attract host capillaries and to enhance neovascularization of the implanted tissue. There are many obstacles to overcome before large, entirely tissue-engineered solid organs are produced. Recent developments in angiogenesis research may provide important knowledge and essential materials to accomplish this goal.

## IX. CLINICAL APPLICATIONS

The assimilation of all these complex technologies into functional bioengineered organs is a complex task. By examining the early attempts at the application of tissue engineering for clinical use, the difficulties and challenges facing scientists in the future are more clearly delineated. The application of bioengineered organs for human use has been addressed in a logical fashion, beginning with the most simple organ system (e.g., skin) and extending to hollow organs (e.g., bladder) and finally to complex solid organs (e.g., kidneys).

### Skin

The concept of the clinical application of skin-tissue engineering had its origins in Massachusetts around 1980, when Yannas and Bell developed the technologies necessary for the growth of skinlike structures from single cells. Bell was able to create dermal skin tissue by culturing human neonatal foreskin fibroblasts in collagen gels (Bell *et al.*, 1979). Yannas and associates expanded this approach, and were able to engineer skin by applying the modern principles of biomaterial scaffolding and molecular cues to influence the growth of skin cells (Yannas and Burke, 1980; Yannas *et al.*, 1980). These efforts resulted in several commercially available bioengineered skin-replacement therapies. Yannas and coworkers developed Integra, a collagen template for dermal regeneration. This was followed shortly by Bell's development of a full-thickness skin substitute with keratinized epidermis and dermis, Apligraf. The most recent development in the skin substitute market is Dermagraft, a composite of dermal fibroblasts and collagen developed by culturing neonatal foreskin fibroblasts on PLGA scaffolds (Shastri, 2006).

Although all these products function well, clinical use has not been widespread. The failure of any of these excellent technologies to dominate the skin-replacement market emphasizes the somewhat-ignored factors of tissue engineering. Mainly, for a technology to be widely accepted as an organ-replacement technology, it must function better than all available options, be easy to use, and not be cost prohibitive. Indeed, a bioengineered organ that functions better than available therapies may never be accepted into widespread clinical use if it is difficult to use or far too expensive.

## Bladder

Currently, gastrointestinal segments are commonly used as tissues for bladder replacement or repair (McDougal, 1992; Kaefer *et al.*, 1997). Because of the problems encountered with the use of gastrointestinal segments, numerous investigators have attempted alternative reconstructive procedures for bladder replacement or repair, such as the use of tissue expansion, seromuscular grafts, matrices for tissue regeneration, and tissue engineering with cell transplantation (McDougal, 1992).

Cell-seeded allogeneic acellular bladder matrices are one of the few strategies of bioengineered bladder replacement with human clinical applications. The early work with this technology was performed in dogs, where a group of experimental canines underwent a trigone-sparing cystectomy with closure of the trigone without a reconstructive procedure or reconstruction with a nonseeded bladder-shaped biodegradable scaffold or reconstruction using a bladder-shaped biodegradable scaffold that delivered seeded autologous urothelial cells and smooth muscle cells (Oberpenning *et al.*, 1999).

The results were promising, with the cystectomy-only and nonseeded controls demonstrating decreased capacities and compliance as compared to preoperative values, while the cell-seeded tissue-engineered bladders showed increased capacity and compliance, with histology depicting normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle (Oberpenning *et al.*, 1999).

Preliminary clinical trials for the application of this technology have been performed and have had promising results. Recently published data demonstrated that engineered autologous bladder tissue may be used safely to augment the bladder in children with end-stage bladder disease secondary to myelomeningocele (Atala *et al.*, 2006). In this study, seven patients aged 4–19 with high pressure or poorly compliant bladders were selected as candidates for autologous augmentation cystoplasty. Bladder biopsies were obtained from each patient, and smooth muscle and urothelial cells were cultured, expanded, and seeded on a composite scaffold. Approximately seven weeks after the biopsy, the autologously generated neobladders were used

for bladder reconstruction with or without omental wrapping. At a mean follow-up of 46 months, the increase in bladder volume and compliance was greatest in the engineered bladders coated in the omental wrap. Bowel function returned promptly after surgery, there were no metabolic complications, no stone formation or mucous production, and renal function was preserved. In addition, engineered-bladder biopsies demonstrated normal structural architecture and phenotype. Thus, this study provided good evidence in support of the use of engineered bladder tissue (created with autologous cells seeded on a composite scaffold and wrapped in omentum following implantation) for patients in need of cystoplasty.

## Kidney

Solid organs are the most challenging to reconstruct by tissue-engineering techniques because of their complex structure and function. Due to these complexities, some scientists approach the replacement of solid-organ function, such as liver or kidney, with bioartificial approaches, combining the function of the organ's predominant cells with an artificial structure and organization.

An example of this strategy is extracorporeal renal replacement. Although dialysis is currently the most prevalent form of renal-replacement therapy, the relatively high morbidity and mortality have spurred investigators to seek alternative solutions involving *ex vivo* systems. In an attempt to assess the viability and physiologic functionality of a cell-seeded device to replace the filtration, transport, metabolic, and endocrinologic functions of the kidney in acutely uremic dogs, a combination of a synthetic hemofiltration device and a renal tubular cell therapy device containing porcine renal tubules in an extracorporeal perfusion circuit was introduced. It was shown that levels of potassium and blood urea nitrogen (BUN) were controlled during treatment with the device. The fractional reabsorption of sodium and water was possible. Active transport of potassium, bicarbonate, and glucose and a gradual ability to excrete ammonia were observed. These results showed the technologic feasibility of an extracorporeal assist device that is reinforced by the use of proximal tubular cells (Humes *et al.*, 1999).

With similar techniques, a tissue-engineered bioartificial kidney consisting of a conventional hemofiltration cartridge in series with a renal tubule-assist device containing human renal proximal tubule cells was used in patients with acute renal failure (ARF) in the intensive care unit. The initial clinical experience with the bioartificial kidney and the renal tubule-assist device suggests that renal tubule cell therapy may provide a dynamic and individualized treatment program as assessed by acute physiologic and biochemical indices (Humes *et al.*, 2003).

The ultimate goal of tissue engineering, however, is the growth of fully functional and fully integrated replacement

organs. Thus, another approach toward the achievement of improved renal function involves the augmentation of renal tissue with kidney cell expansion *in vitro* and subsequent autologous transplantation. The feasibility of achieving renal cell growth, expansion, and *in vivo* reconstitution via tissue-engineering techniques has been explored.

Most recently, an attempt was made to harness the reconstitution of renal epithelial cells for the generation of functional nephron units. Renal cells were harvested and expanded in culture. The cells were seeded onto a tubular device constructed from a polycarbonate membrane, connected at one end with a Silastic catheter that terminated in a reservoir. The device was implanted in athymic mice. Histologic examination of the implanted devices over time revealed extensive vascularization, with formation of glomeruli and highly organized tubulelike structures. Immunocytochemical staining confirmed the renal phenotype. Yellow fluid was collected from inside the implant, and the fluid retrieved was consistent with the makeup of dilute urine in its creatinine and uric acid concentrations (Atala, 2006). Further studies have been performed showing the formation of renal structures in cows via nuclear transfer techniques (Lanza *et al.*, 2002). Challenges await this technology, including the expansion of this system to larger, three-dimensional structures.

## X. CONCLUSION

Tissue-engineering efforts are currently being undertaken for almost every major type of tissue and organ within the body. Most of the effort expended to engineer these organs has occurred since the mid-1990s. Tissue-engineering techniques require a cell culture facility designed for human application. Personnel who have mastered the techniques of cell harvest, culture, and expansion as well as polymer design are essential for the successful application of this technology. Before these engineering techniques can be applied to humans, however, further studies need to be performed in many tissues.

In addition to the challenges already mentioned, numerous other hurdles face the tissue engineers of tomorrow. For example, physiologically accurate bioreactors must be developed and refined if complex organs are to be grown and functionalized prior to implantation in humans. Also, a refinement in the approaches to tissue engineering must be achieved, as scientists explore whether pre-engineered, functional bioengineered replacement organs must be produced to repair tissue function or whether the goal of tissue engineering should be to use simple biomaterials, cells, or growth factors to induce the repair or regrowth of these damaged organs.

### I. INTRODUCTION

The enterprise that has come to be known as tissue engineering had its genesis in the mid-1970s with the pioneering work of Bill Chick on a cell-based bioartificial pancreas (Chick *et al.*, 1977) and of Eugene Bell and Ioannis Yannas with the first fibroblast cell matrix and membrane living-skin surrogates (Bell *et al.*, 1981; Yannas *et al.*, 1982). Significantly, and even before the biotech boom, this work formed the basis for two subsequent early-stage commercial enterprises: Biohybrid and Organogenesis. In the 1980s other scientists extended the grasp of these approaches to the bioartificial liver (Wolf and Munkelt, 1975), kidney (Aebischer *et al.*, 1987), bone (Green, 1977), vascular grafts (Stanley *et al.*, 1982), and the like. Investigators worked in interdisciplinary teams and were funded by the agencies with jurisdiction over the pathologies being investigated. There were no meetings, or even sessions of society meetings, focused on shared themes and common technologies among the various efforts. The term tissue engineering did not exist (Viola *et al.*, 2004), and investigators affiliated with their core disciplines (e.g., endocrinology, engineering) rather than with each other. Commercial activity was low key and fragmented.

Beginning in the late 1980s and early 1990s, a very different landscape began to emerge and take form. Several start-up companies were formed with “deep pocket” venture backing, among them Advanced Tissue Sciences (1986), Organogenesis (1986), and CytoTherapeutics (1989). Baxter and WR Grace began well-funded internal programs related

to the artificial pancreas. Others followed, and the early 1990s were marked by the proliferation of companies in a recognized biotech sector increasingly identified as *tissue engineering*, a term that first appeared in the literature in 1984 (Wolter and Meyer, 1985). The NSF had held a seminal workshop at Granlabbaken (Lake Tahoe) in 1987. Later, under the influence of Robert Nerem, Keystone Conferences on cell biology began to hold sessions on this new field and eventually commissioned fully dedicated conferences. A 1993 *Science* article by Langer and Vacanti (1993) became something of a technological manifesto for involved scientists. Commercial biotechnology conferences began to invite firms to come and tell their story, and firms, ever on the search for more development funds, were delighted to oblige. In 1995, the first issue of the journal *Tissue Engineering* was published. From that time forward, coherent records of the field were maintained that provided adequate documentation of three distinct stages of growth, which will be elaborated and analyzed in this chapter: (1) The age of innocence — the lustrum from 1995 to 2000 saw expansion and growth, unbridled optimism, abundant financing, exuberance, and perhaps a touch of hubris. (2) The perfect storm — between 2000 and 2002, when almost everything that could go wrong in fact did go wrong, leaving a ravaged industrial community and a poorer, sadder, and hopefully wiser cast of players. (3) The present era — from 2003 to the present time, when tissue engineering reinvented itself and has reemerged as a vibrant preclinical developmental industry with ascendant academic overtones. Much

**FIG. 84.1.** The growth of tissue engineering: 1995–2000. During this six-year period, tissue engineering enjoyed a compound annual growth of greater than 15% per year. Cumulative investment exceeded \$3 billion, and nearly all these funds came from the private sector. Left is total annual spending in the field; right is the number of employees.

of the data on which this chapter is based come from a series of our earlier reports in the field of tissue engineering (Lysaght, 1995; Lysaght *et al.*, 1998; Lysaght and Reyes, 2001), some as-yet-unpublished data for the next article in this series, and a very comprehensive NSF-commissioned report on the field (Viola *et al.*, 2004), as well as a comprehensive study describing the course of development in Europe, where things progressed along different paths than in the States (Bock *et al.*, 2003). Methods of data collection and analysis are fully described in these sources.

## II. THE AGE OF INNOCENCE

Figure 84.1 compares the tissue-engineering field in 1995 to that in 2000, using a consistent set of metrics. The number of companies increased from 73 to 89, the number of employees from ~1300 to ~3300, and the annual spending from \$246 million to \$610 million. Most companies were focused on either a specific product or a narrow range of products rather than on platform technologies. Broadly, companies were focused on structural applications (skin, bone, matrices) or on metabolic applications (bioartificial pancreas, bioartificial liver) or, in a few cases, on pure-play cellular applications (certain AIDS and cancer therapies). Virtually all the research and development was conducted in the context of start-ups, especially after Baxter and Grace spun their activities into Novocell and Circe, respectively. Companies could be very small, with fewer than 20 employees or, in some cases, as large as 200 full-time equivalents (FTEs). The smaller enterprises were essentially independent development groups structured as free-standing organizations; their activities were related mostly to early-stage

product development. The larger enterprises were usually structured as full-fledged organizations with all the trappings of an integrated company: separate departments for human resources, law, finance, investor relations, regulatory affairs, and the like. The bulk of activity in these larger organizations was centered on obtaining FDA approval for products believed ready for the market. The executive teams of the larger firms usually involved both scientists and general managers. Two products were approved by 2000: (1) Carticel® cartilage replacement, developed by Applied Biosciences and acquired by Genzyme; and (2) Apligraf®, a living-skin equivalent from Organogenesis. Both products were selling poorly, but this was generally regarded as the “going in” phase, with large-scale revenue soon to follow. Epicel, another skin equivalent, was available from Genzyme but only for compassionate use.

In the absence of robust product sales, from where was to come the revenue to pay for this bustling field? Financially, tissue engineering was modeled on the biotechnology industry, which had begun in the late 1970s and had grown of age in the 1990s, with companies like Amgen, Genentech, and Biogen providing enormous returns to early investors. Although every story was different, the most usual course was for an aspiring tissue-engineering firm to begin with seed money of ~\$500,000 from venture capitalists, which would be followed by a larger investment, usually ~\$5 million from a consortium of venture groups when the firm had recruited a credible scientific advisory board, a strong CEO, and an “investable” scientific staff. Subsequent rounds of financing from “mezzanine” investors would raise another \$10 million to \$20 million, usually on the basis of “unfunded” preclinical results or, better still, early “proof of principle” human trials. Two additional milestones were usually required in order for the firm to go public and raise a significant amount of capital by selling shares on the stock exchange (usually NASDAQ). First, companies needed a corporate partnership, in the form of a marketing and development contract with an established pharmaceutical or medical device company. Examples include ATS partnership with Smith & Nephew, CytoTherapeutics with ASTRA Pharmaceutical, and Organogenesis with Novartis. In these relationships, the corporate partner funded development of a product in return for defined marketing rights. Serious partnerships involved \$20 million to \$50 million, doled out over several years based on the achievement of defined development objectives. In addition to operating cash, the corporate partnership gave a firm considerable credibility in the investment community. The second major prerequisite prior to going public was having a product approved for FDA-level human trials. There were, and are, no uniform regulatory pathways for tissue-engineered products, and the difficulty of initiating FDA trials varied considerably from product to product. In any event, with a corporate partner and a “product in the clinic,” companies were able to go public, raising another \$20 million to \$50 million. Once public, firms could return to the stock market, when

favorable conditions prevailed, to raise more funds to finance further activities. This process was astonishingly successful: By 2000, a total of 16 firms were publicly traded, with a net capital value (number of shares multiplied by price per share) exceeding \$2.5 billion (Lysaght and Reyes, 2001), all this for a field that had yet to produce a single profitable product.

At this juncture, the field of tissue engineering was a uniquely private sector and uniquely American. It is doubtful that government funding ever exceeded 10% of the total spending in any year, probably much less (Hellman, 2000). Academic laboratories operated more as partners with the private sector than as bastions of basic research and fundamental engineering. America had the field to itself — several factors explain the lack of a transatlantic or transpacific component to the field. Europe and the Far East did not have a start-up culture, and individual scientists were uncomfortable with the risk associated with the field. Minimal government support may have been even more of an impediment overseas, where the private sector is more enmeshed with the government than in the United States. And, at least until the close of the era, financing mechanisms for the field (venture capital, mezzanine investment, and public offerings for companies without products) were simply not part of the European or Asian financial rubric.

By the turn of the century, tissue engineering had enjoyed eight years of continuous growth. Sixteen companies were public, and investors with a good sense of timing enjoyed solid returns. Nearly 10 products were in some phase of regulatory-level clinical trials. In an exuberant report on TV's *Good Morning America*, science reporter Michael Gillian opined, "When historians look back, the greatest achievement of the 20th century will not be nuclear power, will not be space travel, will not be microelectronics, but, rather, will be in the fields of tissue engineering and genetic medicine" (Hellman, 2000). Further, *Time* magazine put tissue engineering at the top of its list of "Jobs for the New Millennium" (Atala *et al.*, 2006).

### III. THE PERFECT STORM

The period from 2000 to 2002 was not kind to the field of tissue engineering or to its investors and associated employees. First came the burst of the dot-com bubble and the decline of the NASDAQ. Investors at all stages lost their appetite for risk and sought safe harbors for their funds. Money was scarce; investors demanded higher-risk premiums, and performance was scrutinized closely. Unfortunately it was during this very time frame that the limited potential and flawed market performance of the first three tissue-engineering products were fully discerned. Dermagraft from ATS was introduced to the U.S. market in 2001 and thus joined Carticel (1997) and Carticel (1997). The peak sales of Carticel and Dermagraft were never more than \$20 million per year; such a sales volume does not even cover the fixed cost of a GMP facility to produce a cell-based

product, let alone provide a return on the several hundred million dollars in capital that had been required to bring them to market. Dermagraft sold only a few million dollars worth after its launch. In the face of high operating costs and diminutive sales, both Organogenesis and ATS filed for bankruptcy protection. Together, they had employed over 500 FTEs. Carticel, which had been a separate business unit (Genzyme Tissue Engineering) within Genzyme, was absorbed by Genzyme Surgical Products. The bankruptcy of two of the flagship firms in the field and the downgrading of the third further diminished investor appetite for tissue engineering.

But more bad news was to come. Nine tissue-engineering products had passed phase I clinical trials by 2000; three years later, all nine had either failed in later-phase trials or simply been abandoned (Lysaght and Hazlehurst, 2004). In phase III clinical trials, neither Circe's bioartificial liver nor CytoTherapeutic's cerecrib pain implant had reached statistically significant levels of efficacy, though this is as much a matter of the limited size of the trial population as one of technical device failure. Diacrin's implant for Parkinson's disease was put on clinical hold following incidences of bleeding. Three additional products (two related to bladder leakage and one for improved outcomes following heart bypass) had originally been developed by Reprogenesis and then acquired by Curo. All three products were to be regulated as drugs, and all were abandoned after phase I by Curo, who reckoned that product sales would not be high enough to allow recovery of the cost of clinical trials.

Even in the best of times, the bankruptcies of three flagship companies and nine (of nine) failed pipeline products would have severely challenged the industry. Given the already bad investment climate, the effect was devastating. Nineteen of 89 companies simply shut down, another 27 downsized drastically. About 1800 of 3000 workers in the field had to find new jobs, many in the neighboring field of stem cell research, which by then was beginning to acquire momentum.

Recently it has become fashionable to pronounce that the difficulties of early commercialization resulted from insufficient basic science, but this perspective simply does not stand up to rigorous examination. Rather, the firms failed for a combination of reasons: (1) excessively high manufacturing costs, (2) insufficient attention to reimbursement, (3) poorly structured agreements with marketing partners, (4) unrealistic assessments of the cost-to-benefit ratio of the early products, (5) unrealistic sales forecasts leading to excessive fixed costs of sales, and (6) financial exhaustion after protracted regulatory approval processes. More concisely, it could just be that these firms were good at developing technology but poor at other aspects of the medical products business.

Multiple factors also attend the failure and abandonment of products that had successfully passed the phase I stage. The small size of the study population made stati-

stantial evidence of efficacy a difficult achievement. Circe's bioartificial liver was evaluated on fewer than 100 patients, and CytoTherapeutic's neurocrib implant on only 60 patients. In comparison, 3900 patients received Pfizer's Viagra in its clinical trial and over 5000 patients received J&J's drug-eluting stent. Many argue that larger patient populations for early tissue-engineered products would have led to a statistical demonstration of efficacy, but the companies simply were unable to afford the larger trials. It costs about a billion dollars to bring a drug to market, whereas the development funds available for tissue-engineered products ran at most 15% of this (\$150 million). A second issue is the regulatory pathway: The FDA is on a very steep learning curve with tissue engineering. Some products are treated as devices, including all that eventually reached the market. Some were required to follow the drug pathway, with its higher threshold for approval and a requirement for randomized, blinded trials; no tissue-engineered product assigned to this pathway has yet been approved. Still a third factor is availability of personnel skilled in designing and conducting clinical trials. This is a high-stakes enterprise for pharmaceutical companies, who treat their staff quite generously. It can be difficult for start-ups to acquire the levels of expertise and experience necessary to excel in this field.

In retrospect, one general concern is the appropriateness of the venture capital biotech model to the field of tissue engineering. VCs impose a very Darwinian structure on firms they control and aim for the occasional blockbuster rather than for a string of modest successes. For this reason, diversification of risk by individual start-ups is discouraged. Firms are motivated to grow very large very quickly because large teams have a better chance for the proverbial "home run." Quick growth can mean rushing milestones, such as beginning phase I trials at too early a stage. Finally, VCs are used to the biotech pharmaceutical industry and thus uncomfortable with a slow, cautious, incremental approach, which characterizes successful device development. It is somewhat churlish to be critical of a profession that raised billions of dollars for an unproven technology, but the VCs, like wealthy dysfunctional parents, may have spoiled their offspring.

#### IV. THE PRESENT ERA

Tissue engineering has staged a remarkable comeback and transformation since the dark days of 2002 and 2003. The exact size of the current (mid-2006) industrial sector has not been reported, but our best estimate is that today's firms at least exceed the number from five years previously, with about the same total employment and slightly less overall spending.

Stated differently, there are more companies today than before, but they are smaller and have a lower burn rate per employee. Angels and SBA grants, more so than VCs, provide starting funds. Criteria for series-B or other mezzanine funds have become more rigorous. Although there are

exceptions, investors seem more willing to support early-stage research than to engage in the higher-risk clinical trial phase.

Smith & Nephew retained the marketing rights to ATS' Dermagraft, but sales were diminutive and the product was eventually discontinued. Genzyme's Carticel is placing around 2000–3000 units per year but claims to have reduced manufacturing costs to the point that the operation is profitable at this level. Impressively, Organogenesis, which had fallen to eight employees while under Chapter 11 protection, has rebounded and now claims to be profitable, with ~175 employees and with annual sales approaching 40,000 units. Cumulatively, over 120,000 patients have been treated. Organogenesis has thus become the first TE startup to reach profitability and also the first to reach sustained sales growth. Factors responsible for the turnaround include termination of the original marketing agreement with Novartis, reduced manufacturing costs, enhanced emphasis on sales and marketing, improved packaging, focus on reimbursement, and a clearer appreciation of factors that will predispose dermatologists to adopt the new technology. The product itself has not changed.

Several firms have products in clinical trials. Renamed, which now has over 200 employees, has completed a phase II clinical trial of its bioartificial kidney for the treatment of acute renal failure and has announced plans for a larger, phase III trial. Considerable attention is being paid to the statistical power of the phase III trial, calculable from success rates in the phase I and II trials. Neurotech, a daughter company of CytoTherapeutics, has completed a successful phase II trial of an intraocular implant for the treatment of dry macular degeneration, with a relatively small staff of about 25 employees. Their strategy seems to be to let the staff size dictate the pace of clinical trials; their success certainly contravenes the common wisdom that very large staffs (hundreds or more) are a necessity for FDA trials. The firm has also benefited from clinical trial support from the NIH. Novato has developed vascular grafts from autologous fibroblasts, and these are being tested in a small FDA-approved trial in hemodialysis patients. Intercytex is developing a tissue-engineering lifestyle product to treat male pattern baldness and female alopecia by injecting an expanded population of hair-inductive dermal papilla cells. ReNeuron is developing a cell-carrier system for the treatment of Parkinson's disease. Finally, Aastrom Biosciences has developed a GMP process for collection, expansion, and characterization of bone marrow and is testing the process in a trial application of increasing vascularization in the diabetic foot. Each of these firms is taking a different approach to the clinic, but, importantly, they are refilling the pipeline that became so depleted earlier in the decade.

For completeness, we note the recent attention and publicity that attended the publication of Atala's paper reporting five-year survival of a bioartificial bladder in a series of patients whose bladders had been physically mal-

**Table 84.1. Tissue-engineering/regenerative-medicine meetings in 2006**

<i>Meeting title</i>	<i>Location</i>	<i>Date (2006)</i>
Conference on Epithelial Technologies and Tissue Engineering	Washington, DC	April 2–4
First Chinese European Symposium on Biomaterials in Regenerative Medicine	Suzhou, China	April 3–7
Sixth REGENERATE conference on Tissue Engineering and Regenerative Medicine	Pittsburgh, PA	April 25–27
Third Annual Tissue Engineering Symposium	Tampere, Finland	May 3–5
New developments on polymers for tissue engineering	Maderia, Portugal	June 1–5
Second International Conference “Strategies in Tissue Engineering”	Wurzburg, Germany	May 31–June 2
Advances in Biomaterials for Drug Delivery and Regenerative Medicine	Naples, Italy	June 11–16
Seventh Advanced Summer Course in Cell–Materials Interaction: Regenerative Medicine	Porto, Portugal	June 19–23
Tissue and Cell Engineering Society 2006 — Annual Meeting	Sheffield, England	July 3–4
Thirteenth CIRMIB Biomaterials School “Strategies and Technologies for Tissue Engineering and Reparative Medicine”	Ischia, Italy	July 10–14
Fourteenth annual short course “Advances in Tissue Engineering”	Houston, TX	August 16–19
Annual TERMIS–EU meeting	Rotterdam, Netherlands	October 8–11
Second International Congress on Regenerative Biology	Stuttgart, Germany	October 9–11
Fourth International Symposium “The Science and Technology of Skin Engineering”	Shanghai, China	October 15–17
Sixth Annual Stem Cells and Regenerative Medicine Conference	Pittsburgh, PA	October 16–17
Biomaterials in Regenerative Medicine	Vienna, Austria	October 22–25
ESF-EMBO Symposium on Stem Cells in Tissue Engineering	Sant Feliu de Guixos, Spain	October 28–November 2

formed as a consequence of secondary diseases such as spina bifida (Atala *et al.*, 2006). This achievement was covered as front page news in the *New York Times*, *Wall Street Journal*, and *USA Today*. Major periodicals (*The Economist*, *Time*) also summarized the findings. The publicity was almost universally favorable and uncritical and certainly stands to remove some of the tarnish from the reputation of the field. Commercial rights to this technology are owned by Tengen, which currently has about 40 employees.

Several larger firms have begun to take tissue engineering seriously. Genzyme expanded beyond Carticel to cardiovascular applications (since abandoned) and to a major corporate partnership with Renamed. J&J has established a tissue-engineering division as a business unit to unify and drive all of its activities in the area. Medtronic is reportedly active in the field as well. These are major corporations with deep pockets, regulatory resources, manufacturing capability, and marketing skills. Unlike start-ups, they are not wed to a single product or application and can move from one technology to another as the situation dictates. They will likely have a very positive impact on the future course of commercial tissue engineering.

Globalization is another important trend. Up until the late 1990s, the United States could regard tissue engineering as “mare nostrum”; no longer. A report issued in 2003 and using a very broad definition of tissue engineering lists over 190 business units in the European Union alone (Bock *et al.*, 2003). Some of these are involved in autologous cell transplantation and are quasi-public; others are bona fide private-sector start-ups. England and Germany have established major tissue-engineering centers of excellence, and Holland has a national program in tissue engineering. In the Asian Pacific, Singapore and China are both active, and China, in fact, has two major tissue-engineering centers and Australia has one.

An important trend is the increased academization of the field. Whereas university laboratories used to represent a steady tail on the dizzying kite of industrial tissue engineering, they now have emerged as its center of gravity. The NIH and NSF do not provide tallies of the cumulative extent of their funding in this area, but one need only look at the abstracts at any of the major tissue-engineering meetings to identify the size and scope of the academic contribution. Table 84.1 is an illustrative list of the number of tissue-

engineering meetings held in 2006 (and this does not even count tissue-engineering sessions in more general meetings like ASAI2O and Biomaterials). Nothing could be more indicative of the increased role of academia than this proliferation of meetings, scheduled predominantly during the summer, and their symbiotic societies. Tissue engineering seems to have reversed its earlier practice and is now following the more normal paradigm of early-stage development in academia followed by commercialization by industry.

## V. CONCLUDING PERSPECTIVES

The difficulties and dislocations in tissue engineering early in the first decade of the 21st century were clearly unsettling and unnerving. But a rocky road to the clinic following a brilliant period of discovery and preclinical development is not atypical. Consider the early days of the pharmaceutical industry. Penicillin was first used clinically in the 1920s but did not become a successful commercial product until 25 years later, after World War II. Early difficul-

ties with production of cortisone in the late 1940s nearly bankrupted Merck and forced its merger with Sharpe and Doehme. The polio vaccine survived its early trials and tribulations only because of the finiteness of the alternatives. And then came thalidomide, marking a far lower point than has ever been seen by tissue engineering. But by the mid-1960s, the industry was on its way, and it has become one of the great success stories of contemporary health care. Another example is dialysis for the treatment of end-stage renal disease: The extracorporeal technology was available from the mid-1940s, with workable chronic access available from 1962. But hemodialysis became a widely used therapy for the renal failure population only around 1975. Similar histories attend drug delivery, monoclonal antibody therapy, and the like. Things take time, development is messy, and setbacks and failures are a part of the cycle. But in the end, tissue engineering, with its strong ontologic rationale, still seems predestined to become an important, even dominant, segment of 21st-century medicine.

### I. INTRODUCTION

Therapeutic approaches for replacement, repair, restoration, or regeneration of diseased or damaged human organs or tissues have evolved over the last several years, from human donor organ and tissue transplants and implants of synthetic materials to *in vitro* engineered tissue constructs composed of autologous, allogeneic, or xenogeneic cells coupled with synthetic or natural matrix materials and/or pharmacological agents for either *in vivo* implantation or *ex vivo* use and cell therapies using either native, stem, or progenitor autologous or allogeneic cells for *in vivo* delivery. While organ/tissue transplantation and synthetic material implants continue as the standard of care, donor-organ shortages and indications where such approaches may not be feasible have led to a search for alternatives utilizing living tissue, which, in turn, has provided the impetus for engineered tissue solutions.

Engineered tissues can provide either a structural/mechanical or a metabolic function (Hellman *et al.*, 1998, 2000). Examples published in the scientific literature include, among others: artificial skin constructs; musculoskeletal applications, such as autologous cells for cartilage regenera-

tion, engineered ligament and tendon, and bone graft substitutes; approaches for repair and regeneration of the cardiovascular system, including the myocardium, valves, and vessels; periodontal tissue repair; engineered cornea and lens; spinal cord repair and nerve regeneration; repair of the urogenital system; and approaches for functional restoration of vital metabolic organs, such as the pancreas, liver, and kidney, through either biohybrid organ implants or *ex vivo* support systems.

The promise of engineered-tissue therapies has been realized (Smith and Hellman, 2003; Hellman and Smith, 2006). Skin and musculoskeletal substitutes have been approved for use in the United States by the Food and Drug Administration (FDA). Other applications cited earlier are under either preclinical investigation or regulatory evaluation. Recent advances in stem cell and cytokine biology, materials science, engineering, and computer-assisted modeling and design, among others, are contributing to the development of second-generation engineered-tissue therapies.

In addition to therapeutic applications, *in vitro* engineered-tissue constructs are being applied as biosensors in

diagnostic systems and as test models for toxicity assessment of pharmacological and other agents. Development of enabling technologies provides promising avenues for establishment of a service industry, e.g., cell banks/repositories, scaffold/matrix materials and reference material libraries, and customized tissue-specific bioreactors.

Integrity of the science, together with other critical determinants, is basic to the successful translation of tissue-engineering research into applications for the clinic and the marketplace (Hellman, 2004). Of these determinants, understanding the strategies developed by government entities for providing appropriate product regulatory oversight is key. Since a primary goal is the establishment of a global industry enabling companies to market products across national boundaries, a harmonized international regulatory approach, such as the International Conference on Harmonization for pharmaceutical products, would be ideal. While groups work toward that goal, and recognizing that the public's perception and subsequent market acceptance can be influenced by local social, political, legal, and ethical concerns, it is important to understand the approaches of regulatory entities where the research has moved successfully through product development to the marketplace (Hellman and Smith, 2006). Although the science is now worldwide and regulatory approaches are being developed in Europe and the Far East, among others, this discussion is limited to the regulatory strategies and evolving initiatives in the United States.

The FDA has recognized that an important segment of the products that it regulates results from application of novel technology, such as tissue engineering, and that product applications often pose new and complex issues. Thus, the agency has worked since the early 1990s on developing appropriate strategies for the regulatory oversight of human cells, tissues, and cellular- and tissue-based products. Most, if not all, engineered tissues fall into these categories.

## II. LEGISLATIVE AUTHORITY

### Laws

Since approaches for organ and tissue replacement, repair, restoration, and regeneration and their source materials span a broad spectrum of potential clinical applications, the responsibility for overseeing their development and commercialization within the U.S. federal government has been divided among different regulatory agencies, centers, and offices. The Health Resources Services Administration (HRSA) oversees the National Organ Transplant Program and the National Marrow Donor Program. The remaining products are regulated by the FDA.

The FDA is a science-based regulatory agency in the U.S. Public Health Service (PHS). The agency's legislative authority for product oversight, premarket approval, and postmarket surveillance and enforcement is derived prin-

cipally from the Federal Food, Drug, and Cosmetic (FD&C) Act and the Public Health Service (PHS) Act. Under these authorities, the FDA evaluates and approves products for the marketplace, inspects manufacturing facilities, sometimes before and routinely during commercial distribution, and takes corrective action to remove products from commerce when they are unsafe, misbranded, or adulterated.

### FDA Mission and Organization

The FDA's mission is to promote and protect the public health through regulation of a broad range of products by ensuring the safety of foods, cosmetics, and radiation-emitting electronic products as well as ensuring the safety and effectiveness of human and veterinary pharmaceuticals, biologicals, and medical devices. The FDA's six centers are staffed with individuals expert in the science and regulations appropriate to a center's mission. The centers with regulatory oversight for human medical products are the Center for Drug Evaluation and Research (CDER), which regulates drugs; the Center for Biologics Evaluation and Research (CBER), which regulates biological products; and the Center for Devices and Radiological Health (CDRH), which regulates medical devices and radiation-emitting electronic products. However, each center can apply any of the statutory authorities to regulate its products. For example, many products reviewed by the CBER are regulated under the medical device authority. In addition to the centers, other offices, such as the Office of Regulatory Affairs (ORA) and the Office of Orphan Products (OOP), provide assistance to the centers on regulatory procedures and facility inspections, when necessary. The Office of Combination Products (OCP) is responsible for the regulatory oversight of combination products. Although the office does not perform product reviews for market approval or clearance, it assigns the combination product to the appropriate FDA center, ensures timely and effective premarket review and appropriate postmarket regulation, and serves as a resource to industry and the FDA centers' review staff (Smith and Hellman, 2003; Hellman and Smith, 2006). The OCP serves a very important function for the regulation of engineered tissue products, since many are combination products.

## III. PRODUCT REGULATORY PROCESS

### Classification of Products

Under federal law, a human medical product is classified as either a drug, a biological drug (biologic), a device, or a combination product, e.g., a combination of a drug, a biologic, and/or a device. The product's classification determines the premarket regulatory review and approval process for demonstration of safety and effectiveness utilized by the FDA and the FDA center with lead responsibility and jurisdiction for the product. For example, a *drug* is an article intended for use in the diagnosis, cure, mitigation, treat-

ment, or prevention of disease in humans or other animals and an article (other than food) and other articles intended to affect the structure or any function of the body of humans or other animals [21USC321(g)]. A *biologic* is defined as a virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, or analogous product, . . . applicable to the prevention, treatment, or cure of diseases or injuries of man [42USC262(a)]. A device is an instrument, apparatus, . . . implant, *in vitro* reagent or other similar or related article which is intended for use in diagnosis of disease or conditions or in the cure, mitigation, treatment, or prevention of disease, in humans or other animals, or intended to affect the structure or any function of the body . . . and which does not achieve any of its principal intended purposes through chemical action within or on the body, . . . and which is not dependent on being metabolized for the achievement of any of its principal intended purposes [21USC201(h)].

### Combination Products

Advances in biomedical technology have generated products not readily classifiable as drugs, biologics, or devices as these terms are defined by federal law. To provide for the expanding varieties of products expressing features of more than one of these classifications, the FDA has been authorized to recognize combination products. These products constitute a growing category of innovative medical products. Examples include a drug with an implantable delivery device and autologous cells coupled with a scaffold for orthopedic use. While these products contribute to advancing medical care, they also pose a challenge for the FDA, since they straddle existing statutory classifications of regulated products, complicating the determination of the appropriate regulatory process (Hellman and Smith, 2006).

Congress recognized the existence of combination products when it enacted the Safe Medical Device Act of 1990 and established that the FDA shall classify a combination product according to its primary mode of action [Section 503(g) of the FD&C Act, 21USC353(g)]. From its determination of the product's primary mode of action, the agency could assign jurisdiction over the product to one of its established centers. For example, if the primary mode of action is that of a drug, the product is assigned to CDER, if that of a device to CDRH, and biologics to CBER. The FDA issued a final rule in 1991 establishing the process, i.e., Request for Designation (RFD), by which a product sponsor could petition the agency to make such an assignment [21CFR3.7].

The Medical Device User Fee and Modernization Act of 2002 (MDUFMA) modified Section 503(g) of the FD&C Act to require the FDA to establish an office with the primary responsibility for providing regulatory oversight of combination products. The Office of Combination Products in the Office of the Commissioner assigns the product to the appropriate FDA center, resolves any disputes over a prod-

uct's regulation, and is the focal point for both the FDA staff and industry regarding combination products.

There has been much progress since the office was established in making this somewhat-complex regulatory area more efficient, transparent, and better understood. Because of its role, the office has become the focus and, often, the primary point of entry for sponsors of combination products. The office encourages informal as well as formal interactions, i.e., through the RFD process, with sponsors regarding product jurisdictional questions.

While the FDA has traditionally required sponsors of an RFD to identify the product's primary mode of action and to recommend the lead center for product premarket review and regulation, there is no statutory definition of what constitutes a primary mode of action. To address concerns that, without a statutory codified definition, the assignment process has appeared arbitrary at times, the office published a proposed rule to amend the regulations and to define and codify both mode of action and primary mode of action, "Definition of Primary Mode of Action of a Combination Product: Proposed Rule" (69FR25527, May 7, 2004) (the PMOA Proposed Rule). Almost all comments received from the stakeholder community supported the Proposed Rule in whole or in part. The Final Rule was published on August 25, 2005 (70FR 49848-49862). *Mode of action* is defined as the means by which a product achieves its intended therapeutic effect, i.e., drug, biologic, or device mode of action. Since combination products have more than one identifiable mode of action, the *primary mode of action* is the single mode that provides the most important therapeutic action of the combination product. The *most therapeutic action* is the mode of action expected to make the greatest contribution to the overall intended therapeutic effects of the combination product. The Final Rule also describes an algorithm that the agency would use to assign a product to a center when it cannot determine with reasonable certainty which mode of action provides the most important therapeutic effect. The Final Rule would require a sponsor to base its recommendation of the center with primary jurisdiction for its product by using the definition and, if appropriate, the assignment algorithm. This framework is based on an assessment of the product as a whole, its intended use and effect, consistency with assignment of similarly situated products, and safety and effectiveness issues (Hellman and Smith, 2005c). Of note is that most, if not all, engineered tissue products are combination products.

## IV. PRODUCT PREMARKET SUBMISSIONS

### Investigational Studies

The FD&C Act requires demonstration of safety and effectiveness for new drugs and devices prior to introduction into interstate commerce. The PHS Act requires demonstration of safety, purity, and potency for biological

products before introduction into interstate commerce. Consequently, premarket clinical studies must be performed under exemptions from these laws. For drugs and biologics, which are considered drugs under the FD&C Act, the application for the exemption is an Investigational New Drug (IND) application, (21CFR312). The application for exemption of a device is an Investigational Device Exemption (IDE) (21CFR812).

The contents of IND and IDE applications are similar (Hellman *et al.*, 2000). Applications will include a description of the product and manufacturing processes sufficient for an evaluation of product safety and preclinical studies that have been designed to assess risks and potential benefits of the product. The IND and IDE applications contain a proposal for a clinical protocol, which describes the indication being treated, proposed patient population, patient inclusion and exclusion criteria, treatment regimen, study endpoints, patient follow-up methods, and clinical trial-stopping rules. Both IND and IDE investigations require Institutional Review Board (IRB) approval before they may commence. Although IND and IDE requirements are somewhat different (e.g., in cost-recovery and device risk-assessment areas), the FDA applies comparable standards of safety and effectiveness for either type of application. When the FDA determines that there is sufficient information to allow a clinical investigation to proceed, the IND or IDE exemptions are approved.

The first clinical studies conducted under the IND or IDE applications are often clinical trials involving a small number of individuals (e.g., phase 1/feasibility studies) designed primarily to assess product safety. If these earlier studies indicate reasonable safety, phase 2 studies may be developed to investigate proper and safe dosing and potential efficacy. Phase 3/pivotal studies utilize well-controlled clinical trial designs that support a determination of safety and effectiveness and lead to an application to the FDA for premarket approval of the product.

There may be situations in which the first study under an IND or IDE will not be a phase 1/feasibility study (Hellman *et al.*, 2000). For example, this may occur when there is sufficient clinical experience to establish the safety of a product after use outside the United States or in a different patient population. The FDA may review data from clinical studies performed outside the United States in the IND/IDE process and/or in an application for marketing approval. The agency strongly recommends that the sponsor meet with FDA staff to discuss the clinical protocol, study results, statistical analyses, and applicability of the data to a U.S. population before submitting the premarket submission, i.e., Biologics License or Premarket Approval application (BLA/PMA).

### Premarket Submissions

According to the laws and regulations governing commercial distribution of human medical products, there are

several different types of product premarket submissions, determined by the product's FDA classification. In general, the type of submission will depend on the type of product, i.e., drug, biologic, or device.

Engineered tissue products regulated as biologics will require review and approval of a BLA that demonstrates the safety and effectiveness of the product before it may be marketed commercially. If it is regulated as a device, a PMA demonstrating safety and effectiveness must be approved or a premarket notification [510(k)] must receive clearance. In order to obtain 510(k) premarket clearance, the sponsor must demonstrate substantial equivalence of the device to a legally marketed predicate device.

### Special Product Designations and Submissions

The FD&C Act recognized that there may be situations where the demand for new medical products may be such that the cost of obtaining marketing approval for a product may be prohibitive in view of the small size of the intended population (Hellman and Smith, 2006). To reduce the possibility that a cost-benefit analysis applied to product development for rare diseases will result in no available therapy, the FDA is authorized to grant special consideration and exceptions to reduce the economic burdens on product developers of products under such conditions. As a result, the FDA may be petitioned to grant a Humanitarian Device Exemption (HDE) for certain devices (FD&C Act, 520m) or to recognize certain drugs or biologics as orphan drugs (FD&C Act, 525, et seq.).

A Humanitarian Use Device (HUD) is a product that may be marketed under an exemption for treatment or diagnosis of a disease or condition that affects fewer than 4000 individuals per year in the United States. An HDE exempts an HUD from the effectiveness requirements for devices if certain criteria are met (FD&C Act, 529(m)(1), as amended February 1998). Several engineered skin constructs have been approved for market under the HUD designation.

Orphan drugs are those intended to treat a disease or condition affecting fewer than 200,000 individuals in the United States for which there is little likelihood that the cost of developing and distributing it in the United States will be recovered from sales of the drug in the United States. The orphan drug designation was established through an amendment of the FD&C Act by the 1982 Orphan Drug Act. An orphan drug is defined to include biologics licensed under Section 351 of the PHS Act. Under certain conditions, the FDA has authority to grant marketing exclusivity for an orphan drug in the United States for a period of seven years from the date the drug is approved for clinical use. Other benefits to sponsors include grant support for clinical trials, tax credits for clinical research expenses, and waiver of the prescription drug filing fee (Hellman and Smith, 2006). A sponsor must file a petition for orphan drug designation before any application for marketing approval.

### Postmarket Surveillance

Postmarket surveillance for therapeutic engineered tissue products is an important area of consideration. Manufacturers, user facilities, and health care professionals should report adverse events through the FDA MedWatch process. Postmarketing studies may be necessary when a sponsor seeks a change in product labeling, when studies are a condition of the FDA approval, or when such studies are necessary to protect the public health or to provide safety and effectiveness data (Hellman *et al.*, 2000). Additionally, postmarket surveillance of a device introduced into interstate commerce after January 1, 1991, may be required if it is intended for use in supporting or sustaining human life, presents a potential risk to human health, or is a permanent implant whose failure may cause serious, adverse health consequences or death (Section 522, FD&C Act).

## V. REVIEW OF PRODUCT PREMARKET SUBMISSIONS

Advances in tissue-engineering research have led to potential therapeutic products for many different medical conditions characterized by organ and/or tissue damage. As indicated previously, the products may provide either a structural/mechanical or metabolic function. To date, products have been developed either as *in vitro* engineered tissue constructs for implantation, cell therapies for *in vivo* delivery, or *ex vivo* systems. Representatives of these products are in different stages of development. First-generation products have been approved for use in the United States (Table 85.1), while many others are under either preclinical investigation or regulatory evaluation.

Since many of the products may consist of more than one component, i.e., biomolecule, cell/tissue, and/or biomaterial, they are considered combination products. A determination of the product's primary mode of action dictates the jurisdictional authority for the product and the primary reviewing center, i.e., CDER, CBER, or CDRH. However, regardless of the product's designation, review of any regulated product considers four basic elements [product manufacture, preclinical (laboratory and animal model) testing, clinical performance, and product labeling] in order to determine safety and effectiveness in support of the manufacturer's claim of intended use.

Regulatory evaluation is conducted on a case-by-case basis, and the manufacturer/sponsor is responsible for providing evidence of the product's safety and effectiveness. As indicated, product safety and effectiveness are evaluated with respect to the product's manufacture and clinical performance, as applicable, as well as the manufacturer's claim of intended use, i.e., the patient population to be treated and the product's role in the diagnosis, prevention, monitoring, treatment, or cure of a disease or condition. For engineered tissue products as well as other human medical

products, issues of product manufacture include, among others, cell/tissue, biomaterial, and/or biomolecule sourcing, processing, and characterization; detection and avoidance of adventitious agents; product consistency and stability; and quality control/quality assurance procedures. Other important considerations include evaluation of the preclinical data, e.g., toxicity and immunogenicity testing for local/systemic and acute/chronic responses, as well as assessment of *in vivo* remodeling. Collecting data on product performance in humans requires insight into clinical trial design, e.g., patient entry criteria and study endpoints, study conduct, and subsequent data analyses.

At the request of the sponsor of a new drug, the FDA will facilitate the development and expedite the review of such a drug if it is intended for the treatment of a serious or life-threatening condition and it demonstrates the potential to address unmet medical needs for such a condition. The development program for such a drug or biologic may be designated a fast-track development program and may apply special procedures, such as accelerated approval based on surrogate endpoints, submission and review of portions of an application, and priority review to facilitate its development and expedite its review (Hellman *et al.*, 2000).

For devices, PMAs, PMA Supplements, and 510(k) applications may also undergo expedited review (Hellman *et al.*, 2000). In general, applications dealing with the treatment or diagnosis of life-threatening or irreversibly debilitating diseases or conditions may be candidates for expedited review if the device represents a clear, clinically meaningful advantage over existing technology, the device is a diagnostic or therapeutic modality for which no approved alternative exists, the device offers a significant advantage over existing approved alternatives, or availability of the device is in the best interests of patients. Granted expedited review status means that the marketing application will receive priority review before other applications. When multiple applications for the same type of device have also been granted expedited review, the applications will be reviewed with the priority according to their respective submission due dates.

## VI. HUMAN CELLS, TISSUES, AND CELLULAR- AND TISSUE-BASED PRODUCTS

With the recognition that an important segment of the products that it regulates often arises from applications of new technology, such as tissue engineering, and that the product applications may pose unique and complex questions, the FDA has devoted considerable resources since the early 1990s to the regulatory considerations of what have been termed human cellular- and tissue-based products (HCT/Ps). In February 1997, the FDA proposed a comprehensive tier-based approach for regulation of these prod-

**Table 85.1. FDA-Approved Human Cellular- and Tissue-Based Products (HCT/Ps)**

<i>Skin Applications</i>			
<i>Product</i>	<i>Sponsor</i>	<i>Intended Use</i>	<i>Approval</i>
Carticel (Autologous Cultured Chondrocytes)	Genzyme Corporation	Repair of femoral condyle caused by acute or repetitive fracture	1997-Biologic (BLA)
Apligraf (Viable Allogeneic Fibroblasts/Keratinocytes On Type-1 Bovine Collagen)	Organogenesis Inc.	Standard therapeutic compression for treatment of non-infected partial and full-thickness skin ulcers	1998-Device (PMA)
Dermagraft (Cryopreserved Dermal Substitute; Allogeneic Fibroblasts, Extracellular Matrix, Bioabsorbable Scaffold)	Advanced Tissue Sciences, Inc.	Treatment of full-thickness diabetic foot ulcers	2001-Device (PMA)
Composite Cultured Skin (Viable Allogeneic Fibroblasts/ Keratinocytes On Collagen Matrix)	Ortec International, Inc.	Adjunct to standard autograft procedures for covering wounds and donor sites after surgical release of hand contractions in Recessive Dystrophic Epidermolysis Bullosa patients	2001-Device (HDE)
Dermagraft (Cryopreserved Dermal Substitute; Allogeneic Fibroblasts, Extracellular Matrix, Bioabsorbable Scaffold)	Smith and Nephew Wound Management	Treatment of wounds related to Recessive Dystrophic Epidermolysis Bullosa	2003-Device (HDE)
<i>Musculoskeletal Applications</i>			
<i>Product</i>	<i>Sponsor</i>	<i>Intended Use</i>	<i>Approval</i>
OP-1 Implant (Recombinant Human Osteogenic Protein (rh OP-1), Type-1 Bovine Bone Collagen Matrix)	Stryker Biotech	Alternative to autograft in recalcitrant long bone non-unions	2002-Device (PMA)
In FUSE Bone Graft/LT-Cage Lumbar Tapered Fusion Device (Recombinant Human Bone Morphogenetic Protein-2, Type-1 Bovine Bone Collagen, Titanium Alloy Cage)	Medtronic	Spinal fusion for degenerative disc disease	2002-Device (PMA)
OP-1 Putty (Recombinant Human Osteogenic Protein (rh OP-1), Type-1 Bovine Bone Collagen Matrix, Putty Additive — Carboxymethyl Cellulose Sodium)	Stryker Biotech	Alternative to autograft in compromised patients requiring revision posterolateral lumbar spinal fusion for whom autologous bone and bone marrow-harvest are not feasible or expected to promote fusion	2004-Device (HDE)
GEM 21S™ (Growth Factor Enhanced Matrix) (Recombinant Human Platelet Derived Growth Factor, Synthetic Beta Tricalcium Phosphate)	Biomimetic, Pharmaceuticals, Inc.	Treatment for periodontally-related defects; intrabony defects; furcation defects; gingival recession associated with periodontal defects.	2005-Device (PMA)

ucts, with the level of product review proportional to the degree of risk. On May 25, 2005, the final piece of this regulatory framework was put in place when the Current Good Tissue Practice for Human Cell, Tissues, and Cellular- and Tissue-Based Product Establishments: Final Rule (the CGTP Rule) became effective (Hellman and Smith, 2005a). Two earlier final rules, one providing for establishment registration and the other establishing processes for donor screening, had already set out significant portions of this framework. Publication of the CGTP Rule completes the set of regulations proposed in 1997 and issued in proposed or interim form since 2001 to implement the FDA's framework for regulation of HCT/Ps.

Defined as articles containing or consisting of human cells or tissues that are intended for implantation, transplantation, infusion, or transfer into a human recipient, HCT/Ps include skin, musculoskeletal tissue (bone and ligaments), ocular tissue (especially cornea), heart valve allografts, dura mater, hematopoietic stem and progenitor cells derived from peripheral and cord blood, reproductive tissue, cellular therapies, and combination products consisting of cells/tissue with a device and/or drug (such as cells on a natural or synthetic matrix).

The agency recognized the need for regulatory oversight of these products in the late 1980s and early 1990s because of a number of concerns. First, documented evidence of communicable disease transmission to recipients from infected donor tissue presented a primary public health concern. Second, the rapid growth of the industry with development of new applications and technologies for processing human cells and tissues, coupled with increased demand and international commerce, presented different issues. Finally, voluntary standards established by certain organizations had not been followed uniformly, because they are not legally enforceable. These factors, together with public demand for safe products, compelled the agency to effect appropriate solutions.

The tenets of the tiered risk-based approach initially outlined by the agency have been maintained in the CGTP Rule. Essentially, products meeting certain criteria, so-called *kick-down* factors, would be regulated solely under provisions of Section 361 of the U.S. PHS Act (361 Products) and would not be required to undergo premarket review. All others not meeting the kick-down factors would be regulated under existing drug, biologics, and device regulations, in addition to the new regulations addressing the incorporation of living biological materials into the finished product (Fig. 85.1).

The kick-down factors include minimal manipulation of the source tissue through the processing stage, homologous use, freedom from combination with another article, except a sterilizing, preserving, or storage agent, water, and crystalloids, and absence of intended systemic effect or dependence on the metabolic activity of living cells (except in cases of autologous use, use in first- or second-degree

#### Tiered Approach

- Regulated solely under Section 361 (PHS Act) if all "kick-down" criteria apply:
  - Minimally manipulated
  - Homologous use only
  - Not combined with another article (except sterilizing, preserving, or storage agent, water, or crystalloids)
  - Does not have systemic effect and is not dependent on metabolic activity of living cells (except autologous/reproductive use, use in first-/second-degree blood relatives)
  - Examples: "Banked Human Tissue" – cornea, skin, umbilical cord blood stem cells, cartilage, bone
  - Premarket application not required
- Regulated under Section 361 and biologic (IND/BLA) or device (IDE/PMA) regulations if HCT/P does not meet all "kick-down" criteria.

**FIG. 85.1.** FDA regulatory oversight for cells, tissues, and human cellular- and tissue-based products (HCT/Ps). From Current Good Tissue Practice Final Rule, Published 1/24/2004; Effective 5/25/2005; [www.fda.gov/cber/rules/gtp.htm](http://www.fda.gov/cber/rules/gtp.htm).

blood relatives, or reproductive use). Those HCT/Ps not meeting these criteria would be regulated under the FD&C Act as drugs, biologics, or devices. The risk-based approach is tiered, i.e., stratified, to provide the appropriate type and level of regulation based on a product's characteristics, with a platform of minimal requirements for all cells and tissues and additional requirements when necessary for product safety and effectiveness.

The CGTP requirements cover all aspects of production, including cell and tissue recovery, donor screening and testing, processing and process controls, supplies and reagents, equipment and facilities, environmental and labeling controls, storage conditions, product receipt, predistribution shipment and distribution, advertisement and deviation reporting, and tracking from donor to product consignee. Each establishment of the affected industry must develop and maintain a quality program covering all these requirements and take measures to report and track any product-related adverse event. The CGTP Rule also grants additional provisions to the FDA, including inspection authority, control of imports, and enforcement authority.

Thus, predictable regulatory requirements serve to support innovation in technology and the industry and to minimize elements of uncertainty in the product development process. Since many, if not all, engineered tissues are human cell- or tissue-based and/or combination products, the CGTP Rule and PMOA Final Rule serve to clarify the regulatory requirements for such products and to demonstrate the FDA's commitment to facilitating the development process for these products while, at the same time, maintaining the public confidence in safe, effective medical products for the marketplace.

## VII. SCIENCE AND PRODUCT DEVELOPMENT

Federal investment in basic biomedical research is expected to lead to an overall improvement in public health.

However, as observed and reported by the FDA in its March 2004 report “Challenges and Opportunity on the Critical Path to New Medical Products” (Critical Path Report), that expectation is not being fulfilled, and there is a discontinuity from basic research to application (Hellman and Smith, 2005b).

Data, based on 10-year trends, show that, while there has been an increase in research spending by federal government agencies, such as the National Institutes of Health, and industry, there has been a concomitant decrease in major drug and biological product submissions to the FDA. This is also true for devices, although not to as great an extent.

The FDA’s analysis of this pipeline problem has led to the conclusion that the current medical product development path is becoming increasingly challenging, inefficient, and costly. To address these concerns, the FDA launched the Critical Path Initiative to identify the most pressing obstacles in the path and in technology translation. With publication of the Critical Path Report, the FDA framed the challenge as the shortage of modern tools to enable effective and efficient assessment of the safety and effectiveness of new medical products. Since then, the FDA has worked with FDA staff and external stakeholders to identify the most important challenges and to create the Critical Path Opportunities List as an outline of its strategy to overcome them.

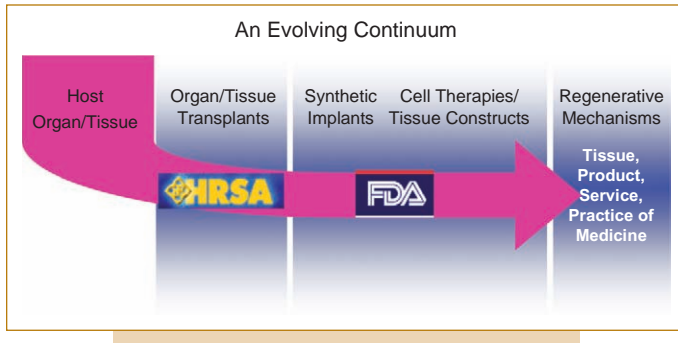

While a number of issues and opportunities have been identified, certain common themes have emerged. The primary concerns are clinical trials and biomarker development. There is a need to improve clinical trials and outcome assessment generally. Accelerating the development and regulatory acceptance of biomarkers or other surrogate markers is perceived as an approach for their use in characterizing the product as well as in measuring outcome(s) for both preclinical and clinical studies. Other areas identified include bioinformatics, manufacturing and scale-up generally, i.e., moving from laboratory bench studies to a manufacturing process with appropriate system design controls to ensure a consistently reproducible, stable product, and progress in evaluating products developed through tissue-engineering approaches. In addition, development of therapies for specific at-risk populations, such as pediatrics, with better extrapolation methods and best practices in clinical trial design was felt to be especially important. It was noted that a key hurdle inhibiting innovation in tissue engineering is the difficulty in sufficiently characterizing the finished product to enable development of meaningful quality controls and product release specifications. For example, conventional techniques for evaluating cell characteristics cannot be applied to these products, since they may also include matrix materials and other components. Consensus on how to assess engineered tissue products and ensure manufacturing consistency would provide developers the predictability needed to fulfill the technology’s full potential.

The initiative will continue as a formal process for continued input from all stakeholders and will be helpful to those engaged in engineered tissues research and product development. The FDA (2006) published the Critical Path Opportunities List and the full Critical Path Opportunities Report on May 16, 2006 (<http://www.fda.gov/oc/initiative/criticalpath>).

## VIII. CONCLUSION AND FUTURE PERSPECTIVES

Strategic investment in science, engineering, and allied disciplines is a critical determinant for advancing both basic and translational research in organ/tissue replacement, repair, restoration, and regeneration toward products for the clinic and the marketplace. However, to achieve successful product commercialization and market penetration, research strategies must be based on sound market analysis and demonstrated clinical need and with a product development plan in place to attract the needed funding support from the financial communities and approval from product regulatory and reimbursement authorities. Understanding the product regulatory process and specific points to consider for engineered human cellular- and tissue-based products will help companies in the development of their overall commercialization strategy. Moreover, since low reimbursement rates can often be the single greatest impediment to product acceptance by end users in the health care environment, attention to cost-recovery issues and their relationship to clinical and economic outcomes is equally important (Norton, 2004). All these determinants are interdependent and must be considered by companies when developing a sound business plan, since uncertainties in any one determinant can have a profound effect on the entire commercialization pathway.

The FDA’s approach to regulation of human cellular- and tissue-based products and combination products as well as other evolving initiatives are indicative of the agency’s commitment to providing the appropriate regulatory oversight for products generated from novel technology, such as tissue engineering. It is expected that the FDA will continue to build on these initiatives and on the cooperative approaches across the appropriate FDA centers and the Office of the Commissioner in its regulatory oversight for engineered tissues so that questions from manufacturers/sponsors are addressed early on in product development, product regulatory jurisdiction questions are addressed in a timely manner, and the product premarket review process becomes more transparent and simplified. This is especially important because the pursuit of new and different research directions focused on tissue and organ regeneration, such as the apparent shift toward the use of stem cell technology (Lysaght and Hazelhurst, 2004), will lead to the development of new and different products, posing unique product-specific issues (Fig. 85.2).

**FIG. 85.2.** Approaches for regulatory oversight of tissue repair, restoration, replacement, or regeneration: an evolving continuum.

The challenges for the tissue-engineering community are similarly multifold. For example, sponsors should consider the important determinants in the product regulatory path, such as the nature of the product, its manufacture and classification, i.e., tissue or product, its mode of action or primary mode of action if a combination product and overall therapeutic approach, and preclinical (animal models) and clinical strategies to assess safety and effectiveness, such as selection of appropriate outcome measures and assessment tools/methods. The sponsor's claim of intended use and whether the product will provide incremental or substantive therapeutic benefit compared to the standard of care will be important for end-user and market acceptance and, ultimately, cost reimbursement. The time to clinic and market will be dependent on the product's classification and subsequent submission and review of sponsor-generated data. For example, an orphan drug or

humanitarian-use device will have a relatively shorter regulatory timeline than a product regulated under existing authorities as a drug, biologic, or device.

To advance the science and minimize the variables in engineered tissue systems, understanding the mechanisms and control processes in normal as well as diseased or damaged human organs and tissues will continue to be a necessary prerequisite for design of novel research strategies focused on applications for tissue repair, restoration, regeneration, and replacement. In this context and to advance the science, the following should continue to be examined: operative mechanisms in cell and developmental biology, interactions of engineered tissue constructs with the host and remodeling by the *in vivo* environment, and acute/chronic as well as local/systemic sequelae of either reparative or regenerative approaches through appropriate preclinical large-animal and clinical-monitoring studies. Progress in biomaterials science, such as the development of matrix materials customized for the cell(s) and application of interest, advances in manufacturing and scale-up techniques, such as development of tissue-customized bioreactors and process system design, and outcomes-assessment tools, such as noninvasive *in vivo* monitoring of implanted engineered tissues, will be important for translating research to applications (Hellman, 2006).

Ultimately, the challenge for the tissue-engineering community is to continue advances in the science while maintaining awareness of the product regulatory environment in the United States and abroad and to be an active voice for articulating the important issues in order to maintain a productive dialogue with the regulatory agencies and consumers so that engineered tissues find their proper place in the clinic and the marketplace.

### I. INTRODUCTION

*Case Study:* The small black box holds a perfectly shaped ear. The scientist at the front of the room explains how it was made. A scaffold of nanoparticles supports fibroblast cells that grew over the form, and the ear now looks and feels actual: It can be transplanted to tissue. For burn patients, this represents an enormous chance and change. It is the prototype of a new genre of medicine, one that uses powerful technologies and methods of bioengineering and cellular biology to transform the matter of the world.

The ear in the box is not a freak example of a new technique. It is, in fact, one of a number of new devices that utilize the convergent technologies of several different fields of science and engineering to create tissue that can mimic the structure and function of the natural world. Other examples include the creation of skin grafts, corneas, bone, cartilage, and, in some pilot studies, bladders. Based on the new technologies of genomics, informatics, nanoscale engineering, molecular biology, and stem cell research, tissue engineering can be said to alter the concept of medicine itself. Instead of treating ailing tissues or organs with drugs intended to repair their structure or function, tissue engineering aims at replacing the diseased or injured or aging

tissues of the body with new ones entirely, made from component parts of the material of the world, both naturally occurring and synthetic.

Such an advance heralds a remarkable ability to heal, a long-awaited solution to several intractable problems, and a serious alternative to cadaveric or living-donor whole organ transplants, which have long been an ethically challenged sector of medicine (Caplan *et al.*, 1994; Fox and Swazey, 1992). Yet such a remarkable construction of the human body asks a great deal of any social world into which it is introduced, for it is the body that is the place of the self, the location of the acts of the sacred, and the sensory arbiter of the real. In fact, tissue engineering queries two of the very aspects of our humanity that we consider distinctive: our integral embodiment and our finitude. If we are indeed a collection of replaceable and adaptable parts, some people reason, what is it that separates us from any other engineered machine? If we can engineer, for example, a synthetic and improved lymphatic system, might we improve our chances to adapt to and overcome infectious disease? What other capacities for healing or alteration of our bodies might be prudent? How do we ensure that such changes are indeed ethical?

It is this query that has greeted the new biotechnologies of the body, one based, this chapter argues, in social reactions largely shaped by culture both ancient and contemporary. We then ask: What are the ethical challenges to the field of tissue engineering? Does tissue engineering raise new ethical issues, or is it a description of one of the modalities enabled by the convergence of other technologies that have been understood to be individually ethically freighted?

In this chapter, I suggest using an established ethical framework that was suggested in 1999 by a committee of the American Association for the Advancement of Science on inheritable genetic germline modification and used far more widely by the field of bioethics to assess new technologies. We then review the responses given to new technologies in the past from a variety of sources in bioethics, philosophy, and theology. Finally, we reflect on how the legal and regulatory structure for tissue engineering has an impact on our reflections on ethical norms (Chapman *et al.*, 2003).

#### Research Evaluation (Adapted from the AAAS Working Group on Human Inheritable Genetic Modifications 1998–2000 (Chapman *et al.*, 2003))

- Are there reasons, in principle, why performing the basic research should be impermissible?
- What contextual factors should be taken into account, and do any of these prevent the development and use of the technology?
- What purposes, techniques, or applications would be permissible and under what circumstances?
- On what procedures and structures, involving what policies, should decisions on appropriate techniques and uses be based?

## II. ARE THERE REASONS, IN PRINCIPLE, WHY PERFORMING THE BASIC RESEARCH SHOULD BE IMPERMISSIBLE?

Principled reasons for objections to basic research are extremely difficult to conceive in research that is, by its very nature, intended to be translational and clinical. Yet ethical objections to the manipulation, replacement, and engineering of human tissue can be seen as part of a long continuum of dissent about medical technology that began to assume full voice in the 1970s, when successful genetic manipulation of bacterial genomes became possible (Walters and Palmer, 1996).

All new technology raises new challenges — in particular, technology that refashions the embodied self, becomes a part of the “self” and the identity of the subject, and seems to raise the deepest anxieties. Even tissue engineering, an emerging field with clear targets, clinical successes, and patient needs, will raise familiar concerns.

First among these is the argument that human’s possess an essential nature and live within an essential natural order that cannot be altered without harm. For C. S. Lewis (1998,

p. 274), this is expressed as a concern that the very acts of rational science — dissection, analysis, and quantification — are a violation of the sacred integrity that lies behind all of nature:

Now I take it that when we understand a thing analytically, and then dominate and use it for our own convenience, we reduce it to the level of “nature,” we suspend our judgments of value about it, ignore its final cause (if any), and treat it in terms of quantity. This repression of elements in what would otherwise be our total reaction to it is sometimes very noticeable and even painful: Something has to be overcome before we can cut up a dead man or a live animal in a dissecting room.

For Lewis, the understanding of the body as replaceable is disturbing: “The real objection,” he says, “is that if man chooses to treat himself as raw material, raw material he will be, not raw material to be manipulated by himself as he fondly imagined, but by mere appetite” (p. 274). (Lewis imagines that new transformative technology will be manipulated by “controllers” who will eventually transform man into mere matter.)

Callahan (1973) echoes Lewis’ concern, both in the sense that limits need to be placed on what is decent to do to nature and in the sense that such action is a part of a larger danger — that power in the hands of medicine to heal is really power in the hands of the elite, or the state, to manipulate and control. He argues:

The word No perfectly sums up what I mean by a limit — a boundary point beyond which one should not go. . . . There are at least two reasons why a science of technological limits is needed. First, limits need to be set to the boundless hopes and expectations, constantly escalating, which technology has engendered. Advanced technology has promised transcendence of the human condition. That is a false promise, incapable of fulfillment. . . . Second, . . . limits (are) necessary in order that the social pathologies resulting from technologies can be controlled. . . . [W]hile it can and does care, save, and free, it can also become the vehicle for the introduction of new repressions in society.

These objections, made over 30 years ago, are still made (despite, one may note with some irony, 30 years of medicine that have indeed seen rapid and successful advances, without their being used by the state for repression and without any fundamental change in the capacities for intellectual and spiritual self-possession). Nevertheless, the powerful arguments of opposition to the manipulation and replacement of tissues and organs continue, with some people worried that perfection itself is sought when healing is the goal. Such critics, many from the disability community, raise principled objections to the use of tissue engineering if the goal is to alter the disability. Activists in the deaf community, for example, defend their disability as a culture and a language exchange, not as a loss of function. Others are concerned that our society’s focus on “fixing things” will allow a devaluation of the persons that currently bear the broken bodies and parts. Adrienne Asche suggests

that there is a “troubling side to every cure, that those of us who are uncured are seen as less valuable, perhaps even expendable.” For Gerald McKenney (1997), a community needs to embrace brokenness and to “deny that the worth of one’s life is determined to how closely one conforms to societal standards of bodily perfection.” McKinney is also concerned that if medicine is successful, it will create a social and economic system that “virtually demands that we be independent of the need to care for others.”

### **Duty and Healing: Natural Makers in a Broken World**

While the opposition to medical technology has indeed been persistent, it has not been unchallenged. For many, the response lies in the nature of brokenness and the human duty to respond to the need of the suffering other (Freedman, 1998; Zoloth, 2003). The principle at stake in the assessment of tissue engineering as an ethical act is not how its use might potentially violate an abstract community in the future, but the actual problem of what one must do as a moral being when one’s neighbor is in need. In this important sense, the duty to heal cannot be overridden by a “sense” of discomfort (as Lewis notes in the earlier quote).

It is the nature, goal, and meaning of science to address the human condition in all its yearning and capacity for defeat and failure. In this sense, there is no principle objection to the science of tissue engineering, and in fact there may well be a strong moral imperative to develop the technology.

Joseph Fletcher (1970) noted, in speaking of an earlier generation of medical technology and answering the critics of science, wrote: “The belief that God is at work directly or indirectly in all natural phenomena is a form of animism or simple pantheism. If we took it really seriously, all science, including medicine, would die away because we would be afraid to ‘dissect God’ or tamper with His activity”. “Every widening and deepening of our knowledge of reality and of our control of its forces are the ingredients of both freedom and responsibility”.

McKinney, Childress, and Lewis use an argument that is rooted in Christian moral theology: that since human persons are fallen creatures in a fallen world, we cannot really be counted on to know the right and the good. God, who is transcendent, from this fallenness, has set us in this place, not essentially to alter it toward our own transonic, but to find its meaning and purpose. Yet other faith traditions differ. For Jewish and Islamic theorists, the world is morally neutral. Human persons may — and will — fail in their aspirations but can be trusted to have the capacity for moral behavior and moral yearnings. Finding meaning in suffering is not the core task. The task is to alleviate suffering, which is understood as chaotic, meaningless, and agonistic. Hence, many of the core objects in principle are rooted in religious constructions and understandings.

### **To Make Is to Know: Notes on an Old Problem About Knowledge**

The classic debates of the 1970s are not the only set of problems engendered in the history of ethical responses to the technological gesture at the heart of tissue engineering. At stake as well is the special kind of knowledge that such making implies. For Aristotle and the Hellenists, useful knowledge, “practical wisdom,” was *phronesis*. *Phronesis* implied actually doing an act, making, in order to know. The act of making, not the act of perception or contemplation alone, how wisdom and, indeed, rationality and power were achieved. Hence, making new tissue is a somewhat different moral gesture than curing the body by altering it with drugs that essentially allow the body to heal itself.

Second, the use of technology within the body of the patient is a different matter than the use of technology essentially to enhance the body of the practitioner. For all earlier technology, the thing that was changed or enhanced was the sense perceptions of the doctor. Stethoscopes and otoscopes allowed the sounds of the body to be more audible. X-rays, CT scans, and MRIs allow the inner vistas of the body to be revealed. EEGs and EKGs allow the electrical currents that animate the central and peripheral nervous systems to be charted in quantifiable units. Microscopes allow invasive bacteria to be seen at the microscopic and, increasingly, molecular levels. These earlier technologies extended the reach of what Bacon increasingly trusted and that the Greeks did not: the perception and observation of the phenomena of the world and the perception of the outcome of its deliberate perturbation.

Bacon’s method presupposes a double empirical and rational starting point. True knowledge is acquired if we proceed from lower certainty to higher liberty and from lower liberty to higher certainty. The rule of certainty and liberty in Bacon converges. . . . For Bacon, making is knowing and knowing is making (cf. Bacon IV [1901], 109–110). Following the maxim “command nature . . . by obeying her” (Sessions, 1999, p. 136; cf. Gaukroger, 2001, pp. 139 ff), the exclusion of superstition, imposture, error, and confusion are obligatory. Bacon introduces variations into “the maker’s knowledge tradition” when the discovery of the forms of a given nature provide him with the task of developing his method for acquiring factual and proven knowledge (Stanford Encyclopedia of Philosophy website, 2003).

Thus, the world is known by understanding the parts of the world and, from that, theorizing (knowing), by induction, to principles or axioms or laws of nature, physics, and chemistry. In contemporary science, knowing is done largely by “unmaking,” by deconstruction of the component parts in ways scientists of Bacon’s era were unable to imagine. Many of these “unmaking” techniques, such as the splicing of alternative DNA and the manipulation of cellular structures, allow a sense of inherent interchangeability, as if the real and the person were merely a set of Lego parts awaiting clever recombination.

### What Is a Thing? The Perils of Deconstruction

Making actual tissue in mimesis of the real tissue of the actual body extends the Baconian act in radical ways. Here, the experimental perturbation is the unmaking of tissue and the remaking of tissue, only in more controllable form. This cannot help but excite concern about the nearly infinite possibilities for technological shaping of the self. Heidegger asks: “What is a thing?” and in so reflecting, understands a thing as an object separate from the self. But what of a made thing, an object that becomes the self?

The technology of the alteration of the patient is distinctive. Devices for altering the functioning of the body that become a part of the body and are actually a tissue of the body are a step beyond the idea of a device held within the body. This is important in any ethical assessment of the technology because the patient’s consent and participation are needed for the final act of the technology to be completed. Such an event only happens in a specific context, for technologies, patients, and practitioners operate in a social, religious, and economic context. Here we turn to the second ethical consideration.

### III. WHAT CONTEXTUAL FACTORS SHOULD BE TAKEN INTO ACCOUNT, AND DO ANY OF THESE PREVENT THE DEVELOPMENT AND USE OF THE TECHNOLOGY?

Tissue engineering is a complex procedure still in experimental stages. Yet to be an ethical technology, it must be directed toward accessibility, just distribution, and efficacy. Hence, the troubling context of widespread health care disparity is a problem not only for this advanced technology but for all newly emerging technologies. Emergence into an unjust world asks certain moral questions of new technological advances. First among these is the query about burdensomeness versus benefit in a context in which the vast majority of the world’s people suffer from easily treatable infectious diseases such as tuberculosis, malaria, AIDS, and infant diarrhea. How can tissue engineering be justly promoted in the face of other, pressing needs?

This objection can typically be met by noting that it would be deeply inappropriate to withhold medical knowledge until the world is entirely perfected and that applications not only will be increasingly available to the poor (as in vaccines, once rare) but also that the very process of research has typically uncovered new and useful ways to understand disease.

The goal of tissue engineering is the widespread use of the technique. Unlike solid-organ transplants, which would always require significant resources far outside the capacities of developing-world clinics, tissue replacement, stem cell therapies, and other transportable therapies are designed for widespread use. The possibility to create a method for

allografts that uses the patient’s own cells and the possibility for allogeneic cells to provide an “off-the-shelf” source of tissue may provide the basis for access (but only if research priorities are discussed in advance of design), a process, as we describe later, that will need careful support and monitoring. The question of how to achieve this and how to enable a more just use of each technology has not yet been solved.

A second contextual factor for tissue engineering is that all human tissue is marked by its genomic identity. It is the very nature of cells, what allows them to copy and reproduce, to carry identifying markers linked to some person somewhere. In the past, such use has raised serious objections. Such tissue can be traced and known, which may have implications for the person who is the source of the tissue, raising significant new issues in genetic privacy for the donor.

Further, whose is the tissue that is derived from the cells of a particular body? Who should have the rights to, and a fair share of, the profits derived from its use? In the seminal case in the field, *Moore v. the Regents of the University of California* (51 Cal 3d 120 271 Cal Reporter, 146, P2d 479, 1990), the issue of ownership was addressed. In this case, Mr. Moore had his T-cell lymphocytes taken from his spleen during the course of treatment for hairy-cell leukemia, cells that proved effective in deriving resistant cell cultures. Patented after manipulation to make a new “product,” the cells were indeed profitable. Mr. Moore’s complaint was that he was not informed of, much less a part of, the scientific enterprise and the lucrative payout for his cells. The case was decided in favor of the research labs. But in the ensuing decades, alert patients with unique cell types or unusual cancers sought for research have been selling their materials as personal possessions to the lab that wishes to procure them. Ownership is limited, however, by the common law of the United States and the European Union which constrains this ability to claim tissue as property. The goals of such restraints were put into place to prohibit the buying and selling of human tissue and organs, for fear, given the desperation of the poor, that selling the bodies of the poor would become permissible and lead to their exploitation. Thus, the entire process that allows for the derivation of tissue sources needs to be noted. The current context for tissue donation is a mixed system. Organs, tissues such as blood, corneas, and marrow are donated or exchanged without compensation. Gametes, however, are another matter entirely. Because the use of human sperm and eggs emerged in the context of fertility treatment and because this treatment was largely conducted in stand-alone, private clinics that functioned without public oversight or regulation, the marketplace standards prevailed. What originally began as a compassionate exchange between family members of gametes when an infertile couple could not conceive quickly changed into a robust marketplace in human gametes. As of this writing, international standards

prohibit the use of marketplace incentives for gametes or embryos (International Society for Stem Cell Research, 2006).

A final context for the debate about the ethics of tissue engineering in general is the special case of human stem cells to make tissues. Because some applications of tissue engineering use stem cells as a part of the method of treatment (Egan, 2006), the debate about the ethics of the use of human stem cells is directly adjacent to this technology. For many, the origins of tissue matter a great deal. For some Christians, many Roman Catholics, and some Hindu sects, the destruction of the human embryo, even at the blastocyst stage, is tantamount to killing. For these faith traditions, the derivation of stem cells from embryos is always impermissible. For many other faith traditions, such as Judaism, Islam, Jainism, Buddhism, Confucian philosophy, and Daoism, the use of these cells is permissible within certain constraints, as we will see later. For all faith traditions, however, the manipulation of adult somatic cells in their precursor form is completely sanctioned. Precursor cells are not as flexible as pluripotent cells, and it is that very pluripotency and immortality that are important in tissue engineering. These factors raise concern. Yet the contextual factors alone do not prohibit entirely the use of this technology, for justice in distribution, the possibility of the loss of genetic privacy, and the controversy over stem cell research when pluripotent embryonic cells are used affect many aspects of the new techniques in medicine. Hence, we turn to the third major issue.

#### **IV. WHAT PURPOSES, TECHNIQUES, OR APPLICATIONS WOULD BE PERMISSIBLE AND UNDER WHAT CIRCUMSTANCES?**

Many of the salient, justifying arguments for the use of tissue engineering hinge on the telos, or goal, of the treatment: If the goal is to cure or treat human disease, then the benefits will outweigh the burdens of the work — controversy, cost, and difficulty. Clearly, then, tissue engineering ought not to be used in a trivial or wasteful fashion. Human tissue is understood by many as deserving a special sort of “respect” (Geron Ethics Advisory Board, 1999; Nelson, 2002).

This proviso may not be so simple, for a core problem in genetic engineering has been the use of the technique for “enhancement” of human characteristics or traits. The initial ethical discussions about therapeutic uses of medicine versus cosmetic ones imagined ethical bright lines that would define the boundary between the use of such technology to restore “species normal functions” (Daniels, 1996) for each tissue and for the person as a whole. Yet medical practice has long gone beyond these lines, using surgery, for example, for cosmetic purposes. Will it be possible to restrict tissue replacement to burn victims, spinal cord injury, and diabetics? How can such a distinction be made?

Some tissue-replacement therapies, such as the use of skin grafts for full-face transplant, may also raise questions about the nature of identity. Indeed, the notion of a full-face transplant alerted us to the depth of resistance to identity-altering tissue replacements. (Could persons use any face? What if persons in need of facial transplants wished to change ethnicity? Should faces “match,” and why?) Like many other aspects of this technology, this tension about identity was not new, only heightened. For example, the first years of organ transplant raised the same issues for recipients of hearts, a key aspect of identity in many cultures. If the face is our key determinant of the self in modernity and, even more so, if the brain is such, then how are we to understand the use of tissue engineering to transform identity?

Hence, linked inexorably to this technology are larger considerations of the use of tissue engineering for neuroscience, both for therapy and for enhancement. The applications of tissue transplant in Parkinson’s disease are important. Yet will there be concern about this use of the neurons of a stranger in the brain of the self? Of all the possible uses of tissue engineering, the ones that may alter consciousness and memory are the most troubling. (What capacities or memories could neurons store?) Here, the need for restrictions on applications may be the clearest, yet it is not clear who ought to decide and who ought to ensure that the restrictions on unethical applications are maintained. By what criteria will such limits be set?

New research possibilities also offer applications to engineer gametes for use and storage. Engineered follicles may now be saved, frozen, matured, and used in animal models to create the possibility of human fertility after cancer chemotherapy or other environmental risk (Woodruff *et al.*, 2006).

With this, as with all such technology, there will have to be careful attention to how the market may drive technology toward specific research goals rather than others or to whether research goals will be framed only by the values of profit and efficacy and not by ones of more general interest: compassion, healing, and solidarity. The powerful applications and the potential for widespread use itself create the possibility for serious conflicts of interest, for serious market forces may be the core drivers of technology, especially in an aging population with increasing needs for all manner of new tissues and organs. This turns us to the consideration of our final set of issues.

#### **V. ON WHAT PROCEDURES AND STRUCTURES, INVOLVING WHAT POLICIES, SHOULD DECISIONS ON APPROPRIATE TECHNIQUES AND USES BE BASED?**

Much of the first reviews of the ethical issues in tissue engineering have in fact focused on the issues of policy:

safety, patents, and gating. Products and drugs are typically controlled via four levels of restraints. The first is elaborate premarket gating, first involving animal models and then typically done for pharmaceuticals in a decade-long series of tests, phased to test the drug on an increasing but controllable number of human subjects. Such trials must be gender balanced, and subjects must give full, informed consent and be able to leave the trial at any time (which could be difficult in cases of implanted tissues).

The next gating is the system of intellectual property. Patents and licensing control the use of the products, even the replication of the experiments. The next gating is that of financial backing. To perform the enormous clinical trials, to do premarket investigation, and, of course, actually to make and sell the product require a production apparatus, which must be assembled and supported. Finally, each drug or device must be approved for use by the insurers. As David Smith (2004) notes, tissue engineering faces a gauntlet of issues and a “new order of magnitude in interactions and science patents.” Additionally, notes Smith, the “things” engineered are hybrids of two jurisdictions, that of drugs and that of devices.

Are genetically engineered insulin cells a drug, like insulin, a device, like a stent, or a biologic? Unlike stents, which are entirely synthetic, tissue engineering uses actual human cells, only manipulated in *de nova* ways.

Standards will need to be set for safety, efficacy, and fair use. Standards for clinical use, standards for clinical trial, and standards for tissue stability and purity will be needed for the research and application to be safe.

Getting informed consent in this case will present significant challenges. Patients in need of organs, for example, are particularly desperate, and their consent may be deeply affected by their utter lack of options. Eight percent of the medical system is already devoted to organ transplantation, and the lack of organs is an overwhelming problem for nearly half of the patients hoping for transplants (Lysaught and O’Leagh, 2001). Yet the first year of the use of engineered tissue will be experimental and will need to be conducted under the strongest possible set of NIH guidelines. How the first trials of engineered tissue are conducted will set the tone and the future for all subsequent use.

The question of policy and the regulation of policy are manifested in many of the first documents that evaluate the ethical and legal implications of tissue engineering. While,

as Smith notes, the United States faces a complex regulatory system, the European Union has regulated such research products as medical products, and these will fall under the regulatory gaze of the European Medical Evaluation Agency (EMA). In both the United States and the EU, the synthetic nature of tissue engineering, the very *de novo* quality of the work, and the uneasy greeting that met genetically modified food has created serious political opposition. Policies need to be crafted with transparency and full public participation, for such research needs not only public funding but public understanding of complex theory and practice of tissue engineering — what promises it can hold and what cautions need to be applied prior to use. Policymakers will need to attend to calls for justice in distribution, as was noted earlier, and will need to set in place structures for regulation.

How can new technologies best be regulated? I contend that a full array of regulatory structures can be employed. First among these are local committees, IRBS, and local review boards. The National Academies have played a large role in policy writing for both recombinant DNA and for stem cell research and, in both instances, called for special, national, ongoing oversight on such research. It would be prudent to reflect on the need for such a process for tissue engineering, for established structures largely address issues involving the use of donated tissue, not engineered tissue. Structures that protect human subjects also need strong enforcement, as noted earlier, both for donors and for recipients of tissues.

But regulation, government oversight, and market forces can only go so far in shaping just research goals and commitments. The goal of ethics is to develop moral agents who are aware of a constancy of duty toward subject and to humanity, who not only follow rules correctly but who, given the chance and grace to work at the frontiers of science, act with courage and decency in their research.

## VI. CONCLUSION

Tissue engineering suggests that an old dream — the replacement of human body parts — may be realized. While any sober and reflective scientist understands the long way to success of this idea, the science described in this volume clearly suggests that our society is on the road to the enactment of the possibility.

# Epilogue

This volume represents a current snapshot of tissue engineering, a single frame in a video sequence of ideas, science, and technological development spanning 30 years. The script evolves in real time and now includes substantive work in stem cell biology. Terms evolve as well. *Regenerative medicine* has been added to the nomenclature. Also included is a catalogue of clinical work, not only commercial prod-

ucts but clinical trials. Business models have been tested and will continue to be adapted to maximize translation of innovation into patient care. New updates will continue as long as progress in the field continues to excite young and creative minds.

*Joseph Vacanti*

- contraction and extracellular matrix organization, 1156–1157
- granulation tissue
  - fibroplasia components, 1152–1155
  - formation, 1152, 1161
- impairment mechanisms, 1170–1172
- inflammation, 1150
- living-skin equivalent model, 246–247
- organ injury, *see* Regeneration *in vivo*
- overview, 1169–1170
- platelet-derived growth factor
  - acceleration of healing, 197–199, 1149
  - role, 194, 195
- re-epithelialization, 1150–1152, 1174
- stages, 194, 199
- tissue engineering
  - dermal constructs, 1158–1159
  - epidermal constructs, 1158
  - prospects, 1159–1161
  - skin substitutes, 1159
- wound types in clinic, 1149
- Xenogeneic cell, definition, 8
- YISGR sequence
  - adhesion proteins, 300
  - polymer modification, 287
- Young's modulus
  - elasticity, 256–257
  - measurement, 257–259
